ISBN 0-07-034032-3

The sponsoring editor for this book was Linda Ludewig, the editor supervisor was David Fogarty, and the production supervisor was Pamela A. Pelton. It was set in Century Schoolbook by D&G Limited, LLC.

Printed and bound by R. R. Donnelley & Sons Company.

McGraw-Hill books are available at special quantity discounts to use as premiums and sales promotions, or for use in corporate training programs. For more information, please write to the Director of Special Sales, Professional Publishing, McGraw-Hill, Two Penn Plaza, New York, NY 10121-2298. Or contact your local bookstore.

Information contained in this work has been obtained by The McGraw-Hill Companies, Inc. ("McGraw-Hill") from sources believed to be reliable. However, neither McGraw-Hill nor its authors guarantee the accuracy or completeness of any information published herein and neither McGraw-Hill nor its authors shall be responsible for any errors, omissions, or damages arising out of use of this information. This work is published with the understanding that McGraw-Hill and its authors are supplying information but are not attempting to render engineering or other professional services. If such services are required, the assistance of an appropriate professional should be sought.

This book is printed on recycled, acid-free paper containing a minimum of 50 percent recycled de-inked fiber.

|--------------------------------------|---------|
| <i>List of Contributors</i> | / ix |
| <i>Preface to the Third Edition</i> | / xvii |
| <i>Preface to the Second Edition</i> | / xix |
| <i>Preface to the First Edition</i> | / xxi |
| <i>SI Units—A Commentary</i> | / xxiii |

| | | |
|------------------|--|------------|
| Chapter 1 | Introduction: Classification and Selection of Pumps | 1.1 |
|------------------|--|------------|

| | | |
|------------------|--------------------------|------------|
| Chapter 2 | Centrifugal Pumps | 2.1 |
|------------------|--------------------------|------------|

| | | |
|-------|---|---------|
| 2.1 | Centrifugal Pump Theory | / 2.3 |
| 2.2 | Centrifugal Pump Construction | / 2.97 |
| 2.2.1 | Centrifugal Pumps: Major Components | / 2.97 |
| 2.2.2 | Centrifugal Pump Packing | / 2.183 |
| 2.2.3 | Centrifugal Pump Mechanical Seals | / 2.197 |
| 2.2.4 | Centrifugal Pump Injection-Type Shaft Seals | / 2.239 |
| 2.2.5 | Centrifugal Pump Oil Film Journal Bearings | / 2.247 |

- 2.2.6 Centrifugal Pump Magnetic Bearings / 2.277
- 2.2.7 Sealless Pumps / 2.295
 - 2.2.7.1 Magnetic Drive Pumps / 2.297
 - 2.2.7.2 Canned Motor Pumps / 2.315
- 2.3 Centrifugal Pump Performance / 2.327
 - 2.3.1 Centrifugal Pumps: General Performance Characteristics / 2.327
 - 2.3.2 Centrifugal Pump Hydraulic Performance and Diagnostics / 2.397
 - 2.3.3 Centrifugal Pump Mechanical Performance, Instrumentation, and Diagnostics / 2.405
 - 2.3.4 Centrifugal Pump Minimum Flow Control Systems / 2.437
- 2.4 Centrifugal Pump Priming / 2.453

Chapter 3 Displacement Pumps

3.1

- 3.1 Power Pump Theory / 3.3
- 3.2 Power Pump Design and Construction / 3.21
- 3.3 Steam Pumps / 3.37
- 3.4 Displacement Pump Performance Instrumentation and Diagnostics / 3.63
- 3.5 Displacement Pump Flow Control / 3.75
- 3.6 Diaphragm Pumps / 3.85
- 3.7 Screw Pumps / 3.99
- 3.8 Vane, Gear, and Lobe Pumps / 3.123

Chapter 4 Jet Pumps

4.1

- 4.1 Jet Pump Theory / 4.3
- 4.2 Jet Pump Applications / 4.23

Chapter 5 Materials of Construction

5.1

- 5.1 Metallic Materials of Pump Construction (and Their Damage Mechanisms) / 5.3
- 5.2 Materials of Construction for Nonmetallic (Composite) Pumps / 5.49

Chapter 6 Pump Drivers

6.1

- 6.1 Prime Movers / 6.3
 - 6.1.1 Electric Motors and Motor Controls / 6.3
 - 6.1.2 Steam Turbines / 6.37
 - 6.1.3 Engines / 6.57
 - 6.1.4 Hydraulic Turbines / 6.77
 - 6.1.5 Gas Turbines / 6.89
- 6.2 Speed-Varying Devices / 6.99
 - 6.2.1 Eddy-Current Couplings / 6.99

- 6.2.2 Single-Unit Adjustable-Speed Electric Drives / 6.109
- 6.2.3 Fluid Couplings / 6.127
- 6.2.4 Gears / 6.143
- 6.2.5 Adjustable-Speed Belt Drives / 6.167
- 6.3 Power Transmission Devices / 6.175
 - 6.3.1 Pump Couplings and Intermediate Shafting / 6.175
 - 6.3.2 Hydraulic Pump and Motor Power Transmission Systems / 6.191

Chapter 7 Pump Controls and Valves

7.1

Chapter 8 Pump Systems

8.1

- 8.1 General Characteristics of Pumping Systems and System-Head Curves / 8.3
- 8.2 Branch-Line Pumping Systems / 8.83
- 8.3 Waterhammer / 8.91
- 8.4 Pump Noise / 8.109

Chapter 9 Pump Services

9.1

- 9.1 Water Supply / 9.3
- 9.2 Sewage Treatment / 9.25
- 9.3 Drainage and Irrigation / 9.45
- 9.4 Fire Pumps / 9.57
- 9.5 Steam Power Plants / 9.73
- 9.6 Chemical Industry / 9.113
- 9.7 Petroleum Industry / 9.133
- 9.8 Pulp and Paper Mills / 9.157
- 9.9 Food and Beverage Pumping / 9.187
- 9.10 Mining / 9.197
- 9.11 Marine Pumps / 9.215
- 9.12 Refrigeration, Heating, and Air Conditioning / 9.253
- 9.13 Pumped Storage / 9.261
- 9.14 Nuclear / 9.279
 - 9.14.1 Nuclear Electric Generation / 9.279
 - 9.14.2 Nuclear Pump Seismic Qualifications / 9.301
- 9.15 Metering / 9.313
- 9.16 Solids Pumping / 9.321
 - 9.16.1 Hydraulic Transport of Solids / 9.321
 - 9.16.2 Application and Construction of Centrifugal Solids Handling Pumps / 9.351
 - 9.16.3 Construction of Solids-Handling Displacement Pumps / 9.369
- 9.17 Oil Wells / 9.377
- 9.18 Cryogenic Liquefied Gas Service / 9.399

- 9.19 Aerospace / 9.409
 - 9.19.1 Aircraft Fuel Pumps / 9.409
 - 9.19.2 Liquid Rocket Propellant Pumps / 9.431
- 9.20 Portable Transfer of Hazardous Liquids / 9.441
- 9.21 Water Pressure Booster Systems / 9.447
- 9.22 Hydraulic Presses / 9.463

Chapter 10 Intakes and Suction Piping **10.1**

- 10.1 Intakes, Suction Piping, and Strainers / 10.3
- 10.2 Intake Modeling / 10.39

Chapter 11 Selecting and Purchasing Pumps **11.1**

Chapter 12 Installation, Operation, and Maintenance **12.1**

Chapter 13 Pump Testing **13.1**

Appendix Technical Data **A.1**

Index **I.1**

LIST OF CONTRIBUTORS*

Able, Stephen D., B.S. (M.E.), MBA, M.S. (Eng) SECTION 3.6 DIAPHRAGM PUMPS
Senior Engineering Consultant, Ingersoll-Rand Fluid Products, Bryan, OH

Addie, Graeme, B.S. (M.E.) SUBSECTION 9.16.2 APPLICATION AND CONSTRUCTION
OF CENTRIFUGAL SOLIDS HANDLING PUMPS
Vice President, Engineering and R&D, GIW Industries, Inc., Grovetown, GA

Arnold, Conrad L., B.S., (E.E.) SUBSECTION 6.2.3 FLUID COUPLINGS
Director of Engineering, American Standard Industrial Division, Detroit, MI

Ashton, Robert D., B.S. (E.T.M.E.) SUBSECTION 2.2.4 CENTRIFUGAL PUMP
INJECTION-TYPE SHAFT SEALS
*Manager, Proposal Applications, Byron Jackson Pump Division, Borg-Warner
Industrial Products, Inc., Long Beach, CA*

Bean, Robert, B.A.(Physics), M.S. (M.E.) SECTION 3.6 DIAPHRAGM PUMPS
Engineering Manager, Milton Roy Company, Flow Control Division, Ivyland, PA

Beck, Wesley W., B.S. (C.E.), P.E. CHAPTER 13 PUMP TESTING
*Hydraulic Consulting Engineer, Denver, CO. Formerly with the Chief Engineers Office
of the U.S. Bureau of Reclamation*

Benjes, H. H., Sr., B.S. (C.E.), P.E. SECTION 9.2 SEWAGE TREATMENT
Retired Partner, Black & Veatch, Engineers-Architects, Kansas City, MO

*Note: Positions and affiliations of the contributors generally are those held at the time the respective contributions were made.

Bergeron, Wallace L., B.S. (E.E.) SUBSECTION 6.1.2 STEAM TURBINES
Senior Market Engineer, Elliott Company, Jeannette, PA

Birgel, W. J., B.S. (E.E.) SUBSECTION 6.2.1 EDDY-CURRENT COUPLING
President, VS Systems, Inc., St. Paul, MN

Birk, John R., B.S. (M.E.), P.E. SECTION 9.6 CHEMICAL INDUSTRY
Consultant, Senior Vice President (retired), The Duriron Company, Inc., Dayton, OH

Brennan, James R., B.S. (M.I.E.) SECTION 3.7 SCREW PUMPS; SECTION 9.17 OIL WELLS
Manager of Engineering, Imo Pump, a member of the Colfax Pump Group, Monroe, NC

Buse, Frederic W., B.S. (Marine Engrg.) SECTION 2.2.7.1 SEALLESS PUMPS; MAGNETIC DRIVE PUMPS; SECTION 3.1 POWER PUMP THEORY; SECTION 3.2 POWER PUMP DESIGN AND CONSTRUCTION; SECTION 5.2 MATERIALS OF CONSTRUCTION FOR NONMETALLIC (COMPOSITE) PUMPS; SECTION 9.6 CHEMICAL INDUSTRY
Retired Senior Engineering Consultant, Flowserve Corporation, Phillipsburg, NJ

Cappellino, C. A., B.S. (M.E./I.E.), M.S. (Product Dev't.), P.E. SECTION 9.8 PULP AND PAPER MILLS
Engineering Project Manager, ITT Fluid Technology Corp., Industrial Pump Group

Chaplis, William K., B.S. (M.E.), MBA SECTION 3.1 POWER PUMP THEORY; SECTION 3.2 POWER PUMP DESIGN AND CONSTRUCTION
Product Engineering Manager, Flowserve Corporation, Phillipsburg, NJ

Clopton, D. E., B.S. (C.E.), P.E. SECTION 9.1 WATER SUPPLY
Assistant Project Manager, Water Quality Division, URS/Forrest and Cotton, Inc., Consulting Engineers, Dallas, TX

Cooper, Paul, B.S. (M.E.), M.S. (M.E.), Ph.D. (Engrg.), P.E. CHAPTER 1 INTRODUCTION: CLASSIFICATION AND SELECTION OF PUMPS; SECTION 2.1 CENTRIFUGAL PUMP THEORY; SECTION 2.2.6 CENTRIFUGAL PUMP MAGNETIC BEARINGS; SECTION 2.3.1 CENTRIFUGAL PUMPS: GENERAL PERFORMANCE CHARACTERISTICS; SECTION 9.19.2 LIQUID ROCKET PROPELLANT PUMPS
Retired Director, Advanced Technology, Ingersoll-Dresser Pumps, now Flowserve Corporation, Phillipsburg, NJ

Costigan, James L., B.S. (Chem.) SECTION 9.9 FOOD AND BEVERAGE PUMPING
Sales Manager, Tri-Clover Division, Ladish Company, Kenosha, WI

Cunningham, Richard G., B.S. (M.E.), M.S. (M.E.), Ph.D. (M.E.)
 SECTION 4.1 JET PUMP THEORY
Vice President Emeritus for Research and Graduate Studies and Professor Emeritus of Mechanical Engineering, Pennsylvania State University, University Park, PA

Cutler, Donald B., B.S. (M.E.) SUBSECTION 6.3.1 PUMP COUPLINGS AND INTERMEDIATE SHAFTING
Technical Services Manager, Rexnord Corporation, Warren, PA

Cygnor, John E., B.S. (M.E.) SUBSECTION 9.19.1 AIRCRAFT FUEL PUMPS
Retired Manager, Advanced Fluid Systems, Hamilton Sundstrand, Rockford, IL

Czarnecki, G. J., B.Sc., M.Sc. (Tech.) SECTION 3.7 SCREW PUMPS
Chief Engineer (Retired), Imo Pump, a member of the Colfax Pump Group, Monroe, NC

Dahl, Trygve, B.S. (M.E.), M.S. (M.E. Systems), Ph.D. (M.E.), P.E.
 CHAPTER 11 SELECTING AND PURCHASING PUMPS
Chief Technology Officer, IntellEquip, Inc., Bethlehem, PA. Formerly with Ingersoll-Dresser Pump Co., now part of Flowserve Corporation.

DiMasi, Mario, B.S. (M.E.), M.B.A. SECTION 9.4 FIRE PUMPS

District Manager, Peerless Pump, Union, NJ

Divona, A. A., B.S. (M.E.) SUBSECTION 6.1.1 ELECTRIC MOTORS AND
MOTOR CONTROLS

Account Executive, Industrial Sales, Westinghouse Electric Corporation, Hillside, NJ

Dolan, A. J., B.S. (E.E.), M.S. (E.E.), P.E. SECTION 6.1.1 ELECTRIC MOTORS AND
MOTOR CONTROLS

Fellow District Engineer, Westinghouse Electric Corporation, Hillside, NJ

Dornaus, Wilson L., B.S. (C.E.), P.E. SECTION 10.1 INTAKES, SUCTION PIPING,
AND STRAINERS

Pump Consultant, Lafayette, CA

Drane, John, C.Eng., M.I. Chem.E. SECTION 9.9 FOOD AND BEVERAGE PUMPING
Technical Support Engineer, Mono Pumps Limited, Manchester, England, UK

Eller, David, B.S. (A.E.), P.E. SUBSECTION 6.3.2 HYDRAULIC PUMP AND MOTOR
POWER-TRANSMISSION SYSTEMS

President and Chief Engineer, M&W, Pump Corporation, Deerfield Beach, FL

Elvitsky, A. W., B.S. (M.E.), M.S. (M.E.), P.E. SECTION 9.7 PETROLEUM INDUSTRY
Vice-President and Chief Engineer, United Centrifugal Pumps, San Jose, CA

***Foster, W. E.**, B.S. (C.E.), P.E. SECTION 9.2 SEWAGE TREATMENT
Partner, Black & Veatch, Engineers-Architects, Kansas City, MO

***Fraser, Warren H.**, B.M.E. SECTION 2.3.2 CENTRIFUGAL PUMP HYDRAULIC
PERFORMANCE AND DIAGNOSTICS

*Chief Design Engineer, Worthington Pump Group, McGraw-Edison Company,
Harrison, NJ*

Freeborough, Robert M., B.S. (Min. E.) SECTION 3.3 STEAM PUMPS
Manager, Parts Marketing, Worthington Corporation, Timonium, MD

Furst, Raymond B. SUBSECTION 9.19.2 LIQUID ROCKET PROPELLANT PUMPS
*Retired Manager of Hydrodynamics, Rocketdyne, now The Boeing Company,
Canoga Park, CA*

Giddings, J. F., Diploma, Mechanical, Electrical, and Civil Engineering
SECTION 9.8 PULP AND PAPER MILLS

Development Manager, Parsons & Whittemore, Lyddon, Ltd., Croydon, England

Glanville, Robert H., M.E. SECTION 9.15 METERING
Vice President Engineering, BIF, A Unit of General Signal, Providence, RI

Guinzburg, Adiel, B.Sc. (Aero. E.), M.S. (Aero.), Ph.D. (M.E.)

SUBSECTION 9.19.2 LIQUID ROCKET PROPELLANT PUMPS

*Engineering Specialist, Rocketdyne Propulsion & Power, The Boeing Company,
Canoga Park, CA*

***Gunther, F. J.**, B.S. (M.E.), M.S. (M.E.) SUBSECTION 6.1.3 ENGINES
Late Sales Engineer, Waukesha Motor Company, Waukesha, WI

Haentjens, W. D., B.M.E., M.S. (M.E.), P.E. SECTION 9.10 MINING
Manager, Special Pumps and Engineering Services, Hazleton Pumps, Inc., Hazleton, PA

Hawkins, Larry, B.S. (M.E.), M.S. (M.E.) SUBSECTION 2.2.6 CENTRIFUGAL PUMP
MAGNETIC BEARINGS
Principal, Calnetix, Torrance, CA

Heald, Charles C., B.S. (M.E.) SUBSECTION 2.2.1 CENTRIFUGAL PUMPS: MAJOR
COMPONENTS; SUBSECTION 9.7 PETROLEUM INDUSTRY; SECTION 10.1 INTAKES, SUCTION
PIPING, AND STRAINERS; CHAPTER 12 INSTALLATION, OPERATION, AND MAINTENANCE
*Retired Manager of Engineering, Ingersoll-Dresser Pumps, now Flowserve Corporation,
Phillipsburg, NJ*

Hendershot, J. R., B.S. (Physics) SUBSECTION 6.1.1 ELECTRIC MOTORS AND MOTOR
CONTROLS; SUBSECTION 6.2.2 SINGLE-UNIT ADJUSTABLE-SPEED ELECTRIC DRIVES
President, Motorsoft, Inc., Lebanon, OH

Honeycutt, F. G., Jr., B.S. (C.E.) P.E. SECTION 9.1 WATER SUPPLY
*Assistant Vice President and Head Water Quality Division, URS/Forrest and Cotton,
Inc., Consulting Engineers, Dallas, TX*

House, D. A., B.S. (M.E.) SECTION 9.2 SEWAGE TREATMENT
Product Engineering Manager, Flowserve Corporation, Taneytown, MD

Ingram, James H., B.S. (M.E.), M.S. (M.E.) SUBSECTION 2.3.3 CENTRIFUGAL PUMP
MECHANICAL PERFORMANCE, INSTRUMENTATION, AND DIAGNOSTICS
*Senior Engineering Specialist, Monsanto Fibers and Intermediates Company,
Texas City, TX*

Jackson, Charles, B.S. (M.E.), A.A.S. (Electronics), P.E. SUBSECTION 2.3.3
CENTRIFUGAL PUMP MECHANICAL PERFORMANCE, INSTRUMENTATION, AND DIAGNOSTICS
Distinguished Fellow, Monsanto Corporate Engineering, Texas City, TX

Jaskiewicz, Stephen A., B.A. (Chemistry) SUBSECTION 2.2.7.2 SEALLESS PUMPS:
CANNED MOTOR PUMPS
*Product Manager, Chempump (Division of Crane Pumps & Systems, Inc.),
Warrington, PA*

Jones, Graham, B.S. (M.E.), M.B.A. SUBSECTION 2.2.6 CENTRIFUGAL PUMP MAGNETIC
BEARINGS
Former Project Manager for Magnetic Bearings, Technology Insights, San Diego, CA

Jones, R. L., B.S. (M.E.), M.S. (M.E.), P.E. SUBSECTION 9.7 PETROLEUM INDUSTRY
*Senior Staff Engineer, Shell Chemical Company, Shell Oil Products Company,
Houston, TX*

Jumpeter, Alex M., B.S. (Ch.E.) SUBSECTION 4.2 JET PUMP APPLICATIONS
*Engineering Manager, Process Equipment, Schutte and Koerting Company, Cornwells
Heights, PA*

Kalix, David A., B.S. (C.E.), P.E. (M.E.) SUBSECTION 2.3.4 CENTRIFUGAL PUMP MINIMUM
FLOW CONTROL SYSTEMS
Senior Product Development Engineer, Yarway Corporation, Blue Bell, PA

***Karassik, Igor J., B.S. (M.E.), M.S. (M.E.), P.E.** SUBSECTION 2.2.1 CENTRIFUGAL
PUMPS: MAJOR COMPONENTS; SECTION 2.4 CENTRIFUGAL PUMP PRIMING; SECTION 9.5
STEAM POWER PLANTS; CHAPTER 12 INSTALLATION, OPERATION, AND MAINTENANCE
*Chief Consulting Engineer, Worthington Group, McGraw-Edison Company, Basking
Ridge, NJ*

Kawohl, Rudolph, Dipl. Ing. SECTION 9.4 FIRE PUMPS

Retired Engineering Manager, Ingersoll-Dresser Pumps, now Flowserve Corporation, Arnage, France

Kittredge, C. P., B.S. (C.E.), Doctor of Technical Science (M.E.) SUBSECTION 2.3.1

CENTRIFUGAL PUMPS: GENERAL PERFORMANCE CHARACTERISTICS

Consulting Engineer, Princeton, NJ

Koch, Richard P., B.S. (M.E.) SECTION 9.5 STEAM POWER PLANTS

Manager of Engineering, Pump Services Group, Flowserve Corporation, Phillipsburg, NJ

Kron, H. O., B.S. (M.E.), P.E. SUBSECTION 6.2.4 GEARS

Executive Vice President, Philadelphia Gear Corporation, King of Prussia, PA

***Kurtzsch, W. C.**, B.S. (M.E.), P.E. SI UNITS—A COMMENTARY; CHAPTER 1 INTRODUCTION: CLASSIFICATION AND SELECTION OF PUMPS

Late Director, Research and Development, Engineered Products, Worthington Pump Group, McGraw-Edison Company, Harrison, NJ

Landon, Fred K., B.S. (Aero. E.), P.E. SUBSECTION 6.3.1 PUMP COUPLINGS AND INTERMEDIATE SHAFTING

Manager, Engineering, Rexnord, Inc., Houston, TX

Larsen, Johannes, B.S. (C.E.), M.S. (M.E.) SECTION 10.2 INTAKE MODELING

Retired Vice President, Alden Research Laboratory, Inc., Holden, MA

Lippincott, J. K., B.S. (M.E.) SECTION 3.7 SCREW PUMPS

Vice President, General Manager (Retired), Imo Pump, a member of the Colfax Pump Group, Monroe, NC

Little, C. W., Jr., B.E. (E.E.), D. Eng. SECTION 3.8 VANE, GEAR, AND LOBE PUMPS

Former Vice President, General Manager, Manufactured Products Division, Waukesha Foundry Company, Waukesha, WI

Maxwell, Horace J., B.S. (M.E.) SUBSECTION 2.3.4 CENTRIFUGAL PUMP MINIMUM FLOW CONTROL SYSTEMS

Director of Engineering, Yarway Corporation, Blue Bell, PA

Mayo, Howard A., Jr., B.S. (M.E.), P.E. SUBSECTION 6.1.4 HYDRAULIC TURBINES; SECTION 9.13 PUMPED STORAGE

Consulting Engineer, Hydrodynamics Ltd., York, PA

McCaul, Colon O., B.S., M.S. (Metallurgical Engrg.), P.E. SECTION 5.1 METALLIC MATERIALS OF PUMP CONSTRUCTION

Senior Engineering Consultant, Flowserve Corporation, Phillipsburg, NJ

Messina, Joseph P., B.S. (M.E.), M.S. (C.E.), P.E. SECTION 8.1 GENERAL CHARACTERISTICS OF PUMPING SYSTEMS AND SYSTEM-HEAD CURVES; SECTION 8.2 BRANCH-LINE PUMPING SYSTEMS

Consultant

Miller, Ronald S., B.Sc. (M.E.), B.Sc. (Metallurgical Engrg.)

SECTION 5.1 METALLIC MATERIALS OF PUMP CONSTRUCTION

Manager, Advanced Materials Engineering, Ingersoll-Rand Company

Moll, Steven A., B.S. (E.E.) SECTION 6.2.1 EDDY-CURRENT COUPLINGS

Senior Marketing Representative, Electric Machinery, Minneapolis, MN

- Moyes, Thomas L.**, B.S. (M.E.) SUBSECTION 9.18 CRYOGENIC LIQUEFIED GAS SERVICE
Chief Engineer - R&D, Flowserve Corporation, Tulsa, OK
- Netzel, James P.**, B.S. (M.E.) SUBSECTION 2.2.2 CENTRIFUGAL PUMP PACKING;
SUBSECTION 2.2.3 CENTRIFUGAL PUMPS: MECHANICAL SEALS
Chief Engineer, John Crane, Inc., Morton Grove, IL
- Nolte, P. A.**, B.S. (M.E.) SECTION 9.20 PORTABLE TRANSFER OF HAZARDOUS LIQUIDS
Director of Agricultural Business, Flowserve Corporation, Memphis, TN
- Nuta, D.**, B.S. (C.E.), M.S. (Applied Mathematics and Computer Science), P.E.
SUBSECTION 9.14.2 NUCLEAR PUMP SEISMIC QUALIFICATIONS
Associate Consulting Engineer, Ebasco Services, Inc., New York, NY
- O'Keefe, W.**, A.B., P.E. SUBSECTION 2.3.4 CENTRIFUGAL PUMP MINIMUM FLOW
CONTROL SYSTEMS; CHAPTER 7 PUMP CONTROLS AND VALVES
Editor, Power Magazine, McGraw-Hill Publications Company, New York, NY
- °Olson, Richard G.**, M.E. M.S., P.E. SECTION 6.1.5 GAS TURBINES
*Late Marketing Supervisor, International Turbine Systems, Turbodyne Corporation,
Minneapolis, MN*
- Padmanabhan, Mahadevan**, B.S. (C.E.), M.S. (C.E.), Ph.D., P.E.
SECTION 10.2 INTAKE MODELING
Vice President, Alden Research Laboratory, Inc. Holden, MA
- Parmakian, John**, B.S. (M.E.), M.S. (C.E.), P.E. SECTION 8.3 WATERHAMMER
Consulting Engineer, Boulder, CO
- Parry, W. E., Jr.**, B.S. (M.E.), P.E. SUBSECTION 9.14.1 NUCLEAR ELECTRICAL GENERATION;
SUBSECTION 9.14.2 NUCLEAR PUMP SEISMIC QUALIFICATIONS
*Project Engineering Manager, Nuclear Equipment/Vertical Pumps, Flowserve
Corporation, Phillipsburg, NJ*
- Patel, Vinod P.**, B.S. (M.E.), M.S. (Metallurgical Engrg.), P.E.
CHAPTER 11 SELECTING AND PURCHASING PUMPS
*Senior Principal Engineer, Machinery Technology, Kellogg Brown & Root, Inc.,
Houston, TX*
- Peacock, James H.**, B.S. (Met.E.) SECTION 9.6 CHEMICAL INDUSTRY
Manager, Materials Division, The Duriron Company, Inc., Dayton, OH
- Platt, Robert A.**, B.E., M.E., P.E. SECTION 3.8 VANE, GEAR AND LOBE PUMPS
General Manager, Sales and Marketing, Carver Pump Company, Muscatine, IA
- Pothhoff, E. O.**, B.S. (E.E.), P.E. SUBSECTION 6.2.2 SINGLE-UNIT ADJUSTABLE-SPEED
ELECTRIC DRIVES
*Industrial Engineer (retired), Industrial Sales Division, General Electric Company,
Schenectady, NY*
- Prang, A. J.** SECTION 3.7 SCREW PUMPS
*Manager, Engineering and Quality Assurance, Flowserve Corporation, Brantford,
Ontario, Canada*
- Ramsey, Melvin A.**, M.E., P.E. SECTION 9.12 REFRIGERATION, HEATING, AND
AIR CONDITIONING
Consulting Engineer, Schenectady, NY

- °Rich, George R.**, B.S. (C.E.), C.E., D.Eng., P.E. SECTION 9.13 PUMPED STORAGE
Late Director, Senior Vice President, Chief Engineer, Chas. T. Main, Inc., Boston, MA
- Robertson, John S.**, B.S. (C.E.), P.E. SECTION 9.3 DRAINAGE AND IRRIGATION
Chief, Electrical and Mechanical Branch, Engineering and Construction, Headquarters, U.S. Army Corps of Engineers
- Roll, Daniel R.**, B.S. (M.E.), P.E. SECTION 9.8 PUMP AND PAPER MILLS
Vice President, Engineering & Development, Finish Thompson Inc, Erie, PA
- Rupp, Warren E.** SECTION 3.6 DIAPHRAGM PUMPS
President, The Warren Rupp Company, Mansfield, OH
- Sellgren, Anders**, M.S. (C.E.), Ph.D. (Hydraulics) SUBSECTION 9.16.1 HYDRAULIC TRANSPORT OF SOLIDS; SUBSECTION 9.16.2 APPLICATION AND CONSTRUCTION OF CENTRIFUGAL SOLIDS HANDLING PUMPS
Professor, Division of Water Resources Engineering, Lulea University of Technology, Lulea, Sweden
- Sembler, William J.**, B.S. (Marine Eng.), M.S. (M.E.) SECTION 9.11 MARINE PUMPS
Tenured Associate Professor, United States Merchant Marine Academy, Kings Point, NY
- Shapiro, Wilbur**, B.S., M.S. SUBSECTION 2.2.5 CENTRIFUGAL PUMP OIL FILM JOURNAL BEARINGS
Consultant, Machinery Components, Niskayuna, NY
- Shikasho, Satoru**, B.S. (M.E.), P.E. SECTION 9.21 WATER PRESSURE BOOSTER SYSTEMS
Chief Product Engineer, Packaged Products, ITT Bell & Gossett, Morton Grove, IL
- Smith, L. R.** SECTION 9.18 CRYOGENIC LIQUIFIED GAS SERVICE
Retired, formerly of J. C. Carter Company, Costa Mesa, CA
- Smith, Will**, B.S. (M.E.), M.S. (M.E.), P.E. SECTION 3.5 DISPLACEMENT PUMP FLOW CONTROL; SUBSECTION 9.16.3 CONSTRUCTION OF SOLIDS-HANDLING DISPLACEMENT PUMPS

PREFACE

TO THE THIRD EDITION

It is difficult to follow in the footsteps of Igor J. Karassik, whose vision and leadership played a major role in the concept of a handbook on pumps that is broad enough to encompass all aspects of the subject—from the theory of operation through design and application to the multitude of tasks for which pumps of all types and sizes are employed. That vision was realized in the first edition of the *Pump Handbook*, which appeared a quarter-century ago, with the capable and dedicated co-authorship of William C. Krutzsch, Warren H. Fraser, and Joseph P. Messina. Acceptance of this work globally soon led these distinguished pump engineers to assemble a second edition that not only contained updated material but also presented all numerical quantities in terms of the SI system of units in addition to the commonly used United States customary system of units.

Worldwide developments in pump theory, design and applications have continued to emerge, and these have begun to affect the outlook of pump engineers and users to such an extent that a third edition has become overdue. Pumps have continued to grow in size, speed, and energy level, revealing new problems that are being addressed by innovative materials and mechanical and hydraulic design approaches. Environmental pressures have increased, and these can and are being responded to by the creative attention of pump engineers and users. After all, the engineer is trained to solve problems, employing techniques that reflect knowledge of physical phenomena in the world around us. All of this has led the current authors to respond by adding new sections and by revising most of the others as would be appropriate in addressing these developments. Specifically the following changes should be noted.

Centrifugal pump theory, in the rewritten Section 2.1, proceeds from the basic governing fluid mechanics to the rationale that underlies the fundamental geometry and performance of these machines—while maintaining the concrete illustrations of design examples. A new subsection on high-energy pumps is included.

An update has been made to Section 2.2.1 on major components of centrifugal pumps.

Section 2.3.1 on centrifugal pump general performance characteristics has been updated.

The emerging technology of magnetic bearings is presented in the new Section 2.2.6.

Section 2.2.7, is a new treatment of sealless centrifugal pumps that includes both the canned-motor and magnetically-coupled types.

Chapter 3 on displacement pumps has been reorganized and includes updates of the sections on both reciprocating and rotary positive displacement pumps.

A new Section 4.1 on jet pump theory begins the chapter on jet pumps and deals with liquids and gases for the motive and secondary flows as well as the basics of design optimization.

Chapter 5 on materials of construction, including the Sections 5.1 and 5.2 on metallic and nonmetallic materials respectively, has been completely rewritten and updated.

Chapter 6 on pump drivers has been updated, Section 6.1.1 on electric motors and Section 6.2.2 on adjustable-speed electric drives having been substantially rewritten.

In Chapter 9 on pump services, most of the applications sections have been updated, including those for fire pumps (Section 9.4) and pumps for steam power plants (9.5), pulp and paper (9.8), mining (9.10), metering (9.15), pumped storage (9.13), and nuclear services (9.14).

Section 9.11 on marine applications has been rewritten.

Sections 9.16.1 on hydraulic transport of solids and 9.16.2 on centrifugal slurry pumps are completely new and include several examples.

A new section on aerospace pumps has been added, which includes Sections 9.19.1 on aircraft fuel pumps and 9.19.2 on liquid rocket propellant pumps.

Section 9.20 on handling hazardous liquids is new.

Chapters 10 on intakes and suction piping, 11 on selecting and purchasing pumps and 12 on installation, operation, and maintenance have been updated.

We recognize that further developments are going on apace and that more could have been done. *Computational fluid dynamics* (CFD) and finite-element structural and rotor-dynamic analysis techniques, as well as the revolution in information management and utilization, already promise to profoundly transform pump design, application, and operational practice—and indeed all other areas of engineering endeavor. Nevertheless, we offer this third edition of the *Pump Handbook* as a practical tool for the present day. In this sense, we hope that it will fulfill the vision of the authors of prior editions while at the same time serving as a stepping stone to the future world of pumping.

PAUL COOPER

PREFACE

TO THE SECOND EDITION

Once more, the dubious honor of writing a preface has been bestowed upon me by my three co-editors. And while they are perfectly willing to share the pluses and minuses of collective editorship, they refused to engage in collective “prefaceship,” if I may be allowed to coin a word. At best, they reserved for themselves the right of looking over my shoulder and criticizing the spirit of levity with which I chose to approach the task for which they had unanimously volunteered me. I should add parenthetically that the preface of the first edition (which you can read on the following pages) is actually my fourth draft; the first three were judged too irreverent by my co-editors. (I have preserved these first three drafts for whoever inherits my collection of unpublished material.)

Assuming that my co-editors are more charitable this time, or alternately that our publisher is pressed for time, what follows (if not what precedes) will appear more or less as written.

First of all, we would like to assure the readers of this second edition of the *Pump Handbook* that it is not merely a slightly warmed-over version of the first edition, with such errata as we have spotted corrected and with a few insignificant changes and additions. Actually, the task of rewriting and editing the material in a form that would correspond to what was planned for this second edition proved to be a monumental, not to say awesome, undertaking.

To begin with, in concert with the publishers, it was decided that all data given here would appear in both USCS and SI units. This was not as simple a task as it may appear, for the reason that “absolute” pure SI units do not lend themselves well to the scale of numbers generally encountered in industrial processes. To give but one example, the pascal, which is the SI unit of pressure, corresponds to 0.000145 lb/in^2 , and even the kilopascal is only 0.145 lb/in^2 . Although this might be a reasonably satisfactory unit for scientific work, the case is hardly such for centrifugal pumps used in everyday life.

This led us to choose what might be called a modified set of SI units, all as explained in “SI Units—A Commentary,” on page xxi. Even conveying this desirable concept of a practical set of SI units to the authors of various sections proved to be somewhat difficult.

As a result, we have permitted these authors some leeway in their specific choice, understanding full well that what is desirable in one industry may differ from the preferred choice in another.

We decided that a number of sections and subsections in the first edition could benefit by being significantly expanded. This, for instance, is the case with the following:

- 2.2.1 "Centrifugal Pumps: Major Components"
- 2.3.1 "Centrifugal Pumps: General Performance Characteristics"
- 2.4 "Centrifugal Pump Priming"
- 8.1 "General Characteristics of Pumping Systems and System-Head Curves"
- 8.4 "Pump Noise"
- 9.4 "Fire Pumps"
- 9.15.1 "Nuclear Electric Generation"
- 9.17.1 "Hydraulic Transport of Solids"
- 10.1 "Intakes, Suction Piping, and Strainers"
- Appendix "Technical Data"

At the same time, we felt that some material originally included in the subsection "Centrifugal Pumps: Major Components" should be excised from there and treated in greater depth separately.

This expanded coverage includes the following:

- 2.2.2 "Centrifugal Pump Packing"
- 2.2.3 "Centrifugal Pump Mechanical Seals"
- 2.2.4 "Centrifugal Pump Injection-Type Shaft Seals"
- 2.2.5 "Centrifugal Pump Oil Film Journal Bearings"

Finally, a large amount of subject matter has been added to the second edition:

- 2.3.2 "Centrifugal Pump Hydraulic Performance and Diagnostics"
- 2.3.3 "Centrifugal Pump Mechanical Performance, Instrumentation, and Diagnostics"
- 2.3.4 "Centrifugal Pump Minimum Flow Control Systems"
- 3.3 "Diaphragm Pumps"
- 3.6 "Displacement Pump Performance, Instrumentation, and Diagnostics"
- 3.7 "Displacement Pump Flow Control"
- 5.2 "Materials of Construction of Nonmetallic Pumps"
- 6.3.2 "Magnetic Drives"
- 6.3.3 "Hydraulic Pump and Motor Power Transmission Systems"
- 9.15.2 "Nuclear Pump Seismic Qualifications"
- 9.17.3 "Construction of Solids-Handling Displacement Pumps"
- 9.18 "Oil Wells"
- 9.19 "Cryogenic Liquefied Gas Service"
- 9.20 "Water Pressure Booster Systems"
- 10.2 "Intake Modeling"

In brief, the editors have attempted to increase the usefulness of this handbook. The extent to which we have achieved this objective, we will leave to the judgment of our readers.

PREFACE

TO THE FIRST EDITION

Considering that I had written the prefaces of the three books published so far under my name, my colleagues thought it both polite and expedient to suggest that I prepare the preface to this handbook, coedited by the four of us. Except for the writing of the opening paragraph of an article, a preface is the most difficult assignment that I know. Certainly the preface to a handbook should do more than describe minutely and in proper order the material that is contained therein.

Yet I submit that the saying “a book should not be judged by its cover” should be expanded by adding “and not by its preface.” If the reader will accept this disclaimer, I can proceed.

As will be stated in Section 1, “Introduction and Classification of Pumps,” it can rightly be claimed that no machine and very few tools have had as long a history in the service of man as the pump, or have filled as broad a need in his life. Every process which underlies our modern civilization involves the transfer of liquids from one level of pressure or static energy to another. Pumps have played an essential role in our life ever since the dawn of civilization.

Thus it is that a constantly growing number of technical personnel is in need of information that will help them in either designing, selecting, operating, or maintaining pumping equipment. There has never been a dearth of excellent books and articles on the subject of pumps. But the editors and the publisher felt that a need existed for a handbook on pumps that would present this information in a compact and authoritative form. The format of a handbook permits a selection of the most versatile group of contributors, each an expert on his particular subject, each with a background of experience that makes him particularly knowledgeable in the area assigned to him.

This handbook deals first with the theory, construction details, and performance characteristics of all the major types of pumps—centrifugal pumps, power pumps, steam pumps, screw and rotary pumps, jet pumps, and many of their variants. It deals with prime movers, couplings, controls, valves, and the instruments used in pumping systems.

It treats in detail the systems in which pumps operate and the characteristics of these systems. And because of the many services in which pumps have to be applied, a total of 21 different services—ranging from water supply to steam power plants, construction, marine applications, and refrigeration to metering and solids pumping—are examined and described in detail, again by a specialist in each case.

Finally, the handbook provides information on the selection, purchasing, installation, operation, testing, and maintenance of pumps. An appendix provides a variety of technical data useful to anyone dealing with pumping equipment.

We are greatly indebted to the men who supplied the individual sections that make up this handbook. We hope that our common task will have produced a handbook that will help its user to make a better and more economical pump installation than he or she would have done without it, to install equipment that will perform more satisfactorily and for longer uninterrupted periods, and when trouble occurs, to diagnose it quickly and accurately. If this handbook does all this, the contributors, its editors, and its publisher will be pleased and satisfied.

No doubt a few readers will look for subject matter that they will not find in this handbook. Into the making of decisions on what to include and what to leave out must always enter an element of personal opinion; therefore we will feel some responsibility for their disappointment. But we submit that it was quite impossible to include even everything we had wanted to cover. As to our possible sins of commission, they are obviously unknown to us at this writing. We can only promise that we shall correct them if an opportunity is afforded to us.

IGOR J. KARASSIK

SI UNITS— A COMMENTARY

W.C. KRUTZSCH
P. COOPER

Since the publication of the first edition of this handbook in 1976, the involvement of the world in general, and of the United States in particular, with the SI system of units has become quite common. Accordingly, throughout this book, SI units have been provided as a supplement to the United States customary system of units (USCS). This should make it easier, particularly for readers in metric countries, who will no longer find it necessary to make either approximate mental transpositions or exact mathematical conversions.

The designation SI is the official abbreviation, in any language, of the French title “Le Système International d’Unités,” given by the 11th General Conference on Weights and Measures (sponsored by the International Bureau of Weights and Measures) in 1960 to a coherent system of units selected from metric systems. This system of units has since been adopted by the International Organization for Standardization (ISO) as an international standard.

The SI system consists of seven basic units, two supplementary units, a series of derived units, and a series of approved prefixes for multiples and submultiples of the foregoing. The names and definitions of the basic and supplementary units are contained in Tables 1a and 1b of the Appendix. Table 2 lists the units and Table 3 the prefixes. Table 10 provides conversions of USCS to SI units.

As with the second edition, the decision has been made to accept variations in the expression of SI units that are widely encountered in practice. The quantities mainly affected are pressure and flow rate, the situation with each being explained as follows.

The standard SI unit of pressure, the pascal, equal to one newton^{*} per square meter[†], is a minuscule value relative to the pound per square inch ($1 \text{ lb/in}^2 = 6,894.757 \text{ Pa}$) or to the old, established metric unit of pressure the kilogram per square centimeter ($1 \text{ kgf/cm}^2 =$

^{*}The newton (symbol N) is the SI unit of force, equal to that which, when applied to a body having a mass of 1 kg, gives it an acceleration of 1 m/s^2 .

[†]In countries using the SI system exclusively, the correct spelling is *metre*. This book uses the spelling *meter* in deference to prevailing U.S. practice.

98,066.50 Pa). In order to eliminate the necessity for dealing with significant multiples of these already large numbers when describing the pressure ratings of modern pumps, different sponsoring groups have settled on two competing proposals. One group supports selection of the kilopascal, a unit which does provide a numerically reasonable value ($1 \text{ lb/in}^2 = 6.894757 \text{ kPa}$) and is a rational multiple of a true SI unit. The other group, equally vocal, supports the bar ($1 \text{ bar} = 10^5 \text{ Pa}$). This support is based heavily on the fact that the value of this special derived unit is close to one atmosphere. It is important, however, to be aware that it is not exactly equal to a standard atmosphere ($101,325.0 \text{ Pa}$) or to the so-called metric atmosphere ($1 \text{ kgf/cm}^2 = 98,066.50 \text{ Pa}$), but is close enough to be confused with both.

As yet, there is no consensus about which of these units should be used as the standard. Accordingly, both are used, often in the same metric country. Because the world cannot agree and because we must all live with the world as it is, the editors concluded that restricting usage to one or the other would be arbitrary, grossly artificial, and not in the best interests of the reader. We therefore have permitted individual authors to use what they are most accustomed to, and both units will be encountered in the text.

Units of pressure are utilized to define both the performance and the mechanical integrity of displacement pumps. For kinetic pumps, however, which are by far the most significant industrial pumps, pressure is used only to describe rated and hydrostatic values, or mechanical integrity. Performance is generally measured in terms of total head, expressed as feet in USCS units and as meters in SI units. This sounds straightforward enough until a definition of head, including consistent units, is attempted. Then we encounter the dilemma of mass versus force, or weight.

The total head developed by a kinetic pump, or the head contained in a vertical column of liquid, is actually a measure of the internal energy added to or contained in the liquid. The units used to define it could be energy per unit volume, or energy per unit mass, or energy per unit weight. If we select the last, we arrive conveniently, in USCS units, as foot-pounds per pound, or simply feet. In SI units, the terms would be newton-meters per newton, or simply meters. In fact, however, metric countries weigh objects in kilograms, not newtons, and so the SI term for head may be defined at places in this volume in terms of kilogram-meters per kilogram, even though this does not conform strictly to SI rules.

Similar ambiguity is observed with the units of flow rate, except here there may be even more variations. The standard SI unit of flow rate is the cubic meter per second, which is indeed a very large value ($1 \text{ m}^3/\text{s} = 15,850.32 \text{ U.S. gal/min}$) and is therefore really only suitable for very large pumps. Recently, some industry groups have suggested that a suitable alternative might be the liter per second ($1 \text{ l/s} = 10^{-3} \text{ m}^3/\text{s} = 15.85032 \text{ U.S. gal/min}$), while others have maintained strong support for the traditional metric unit of flow rate, the cubic meter per hour ($1 \text{ m}^3/\text{h} = 4.402867 \text{ U.S. gal/min}$). All of these units will be encountered in the text.

These variations have led to several forms of the specific speed, which is the fundamentally dimensionless combination of head, flow rate, and rotative speed that characterizes the geometry of kinetic pumps. These forms are all related to a truly unitless formulation called "universal specific speed," which gives the same numerical value for any consistent system of units. Although not yet widely used, this concept has been appearing in basic texts and other literature, because it applies consistently to all forms of turbomachinery. Equivalencies of the universal specific speed to the common forms of specific speed in use worldwide are therefore provided in this book. This is done with a view to eventual standardization of the currently disparate usage in a world that is experiencing globalization of pump activity.

The value for the unit of horsepower (hp) used throughout this book and in the United States is the equivalent of 550 foot pounds (force) per second, or 0.74569987 kilowatts (kW). The horsepower used herein is approximately 1.014 times greater than the metric horsepower, which is equivalent to 0.735499 kilowatts. Whenever the rating of an electric motor is given in this book in horsepower, it is the output rating. The equivalent output power in kilowatts is shown in parentheses.

Variations in SI units have arisen because of differing requirements in various user industry groups. Practices in the usage of units will continue to change, and the reader will have to remain alert to further variations of national and international practices in this area.

ABOUT THE EDITORS

Igor Karassik, now deceased, was an original editor of this book. His extensive contributions to the earlier editions remain a signal feature of this edition. A major figure in the pump industry for the greater part of the past century, he also authored or co-authored six books in this field. Beginning in 1936, he wrote more than 600 articles on centrifugal pumps and related subjects, which appeared in over 1500 publications worldwide. For the greater part of his career, he held senior engineering and marketing positions within the Worthington Pump & Machinery Company, which after a number of permutations became part of the Flowserve Corporation. Igor Karassik received his B.S. and M.S. degrees in Mechanical Engineering from Carnegie Mellon University. He was a Life Fellow of the American Society of Mechanical Engineers and recipient of the first ASME Henry R. Worthington Medal (1980).

Joseph P. Messina, also one of the original editors, has spent his entire career in the pump industry; and his past contributions on pump and systems engineering continue to be presented in their entirety in this edition. He served as Manager of Applications Engineering at the Worthington Pump Company. He became a Pump Specialist at the Public Service Electric and Gas Company in New Jersey, serving as a committee member of the Electric Power Research Institute to improve the performance of boiler feed pumps. He assisted in updating the Hydraulic Institute Standards and taught centrifugal pump courses. He also taught Fluid and Solid Mechanics at the New Jersey Institute of Technology and holds a B.S. in Mechanical Engineering and an M.S. in Civil Engineering from the same institution. Now a pump technology consultant, he has been a contributor to the technical journals and holds pump-related patents.

Paul Cooper has been involved in the pump industry for over forty years. He began by specializing in the hydraulic design of centrifugal pumps and inducers for aerospace applications at TRW Inc. This was followed by a career in research and development on pump hydraulics and cavitation at the Ingersoll-Dresser Pump Company, now part of the Flowserve Corporation, where he conducted investigations at the Ingersoll-Rand Research Center and later served as the director of R&D for the company. A Life Fellow of the ASME, he received that society's Fluid Machinery Design Award (1991) and the Henry R. Worthington Medal (1993). He received his B.S. (Drexel University) and M.S. (Massachusetts Institute of Technology) degrees in Mechanical Engineering and a Ph.D. in Engineering from Case Western Reserve University. Now a consultant, he is the author of many technical papers and holds several patents on pumps.

Charles C. Heald has spent his entire career in the pump industry. He conducted the hydraulic and mechanical design of several complete lines of single and multistage pumps for the Cameron Pump Division of Ingersoll-Rand, which became part of the Ingersoll-Dresser Pump Company. He served as Chief Engineer and Manager of Engineering. Currently a consultant, he continues to function as the editor of the company's *Cameron Hydraulic Data Book*. The petroleum industry has always been the focus of his efforts, and he has served for over 35 years as a member of the API 610 specification task force, receiving a resolution of appreciation from API in 1995. A Life Member of the ASME, he obtained the B.S. degree in Mechanical Engineering from the University of Maine, and he is the author of several technical articles and the holder of patents pertaining to pumps.

**INTRODUCTION:
CLASSIFICATION
AND
SELECTION
OF
PUMPS**

W. C. Krutzch

Paul Cooper

INTRODUCTION

Only the sail can contend with the pump for the title of the earliest invention for the conversion of natural energy to useful work, and it is doubtful that the sail takes precedence. Because the sail cannot, in any event, be classified as a machine, the pump stands essentially unchallenged as the earliest form of machine for substituting natural energy for human physical effort.

The earliest pumps we know of are variously known, depending on which culture recorded their description, as *Persian wheels*, *waterwheels*, or *norias*. These devices were all undershot waterwheels containing buckets that filled with water when they were submerged in a stream and that automatically emptied into a collecting trough as they were carried to their highest point by the rotating wheel. Similar waterwheels have continued in existence in parts of the Orient even into the twentieth century.

The best-known of the early pumps, the Archimedean screw, also persists into modern times. It is still being manufactured for low-head applications where the liquid is frequently laden with trash or other solids.

Perhaps most interesting, however, is the fact that with all the technological development that has occurred since ancient times, including the transformation from water power through other forms of energy all the way to nuclear fission, the pump remains probably the second most common machine in use, exceeded in numbers only by the electric motor.

Because pumps have existed for so long and are so widely used, it is hardly surprising that they are produced in a seemingly endless variety of sizes and types and are applied to an apparently equally endless variety of services. Although this variety has contributed to an extensive body of periodical literature, it has also tended to preclude the publication of comprehensive works. With the preparation of this handbook, an effort has been made to create just such a comprehensive source.

Even here, however, it has been necessary to impose a limitation on subject matter. It has been necessary to exclude material uniquely pertinent to certain types of auxiliary pumps that lose their identity to the basic machine they serve and where the user controls neither the specification, purchase, nor operation of the pump. Examples of such pumps would be those incorporated into automobiles or domestic appliances. Nevertheless, these pumps do fall within classifications and types covered in the handbook, and basic information on them may therefore be obtained herein after the type of pump has been identified. Only specific details of these highly proprietary applications are omitted.

Such extensive coverage has required the establishment of a systematic method of classifying pumps. Although some rare types may have been overlooked in spite of all precautions, and obsolete types that are no longer of practical importance have been deliberately omitted, principal classifications and subordinate types are covered in the following section.

CLASSIFICATION OF PUMPS

Pumps may be classified on the basis of the applications they serve, the materials from which they are constructed, the liquids they handle, and even their orientation in space. All such classifications, however, are limited in scope and tend to substantially overlap each other. A more basic system of classification, the one used in this handbook, first defines the principle by which energy is added to the fluid, goes on to identify the means by which this principle is implemented, and finally delineates specific geometries commonly employed. This system is therefore related to the pump itself and is unrelated to any consideration external to the pump or even to the materials from which it may be constructed.

Under this system, all pumps may be divided into two major categories: (1) dynamic, in which energy is continuously added to increase the fluid velocities within the machine

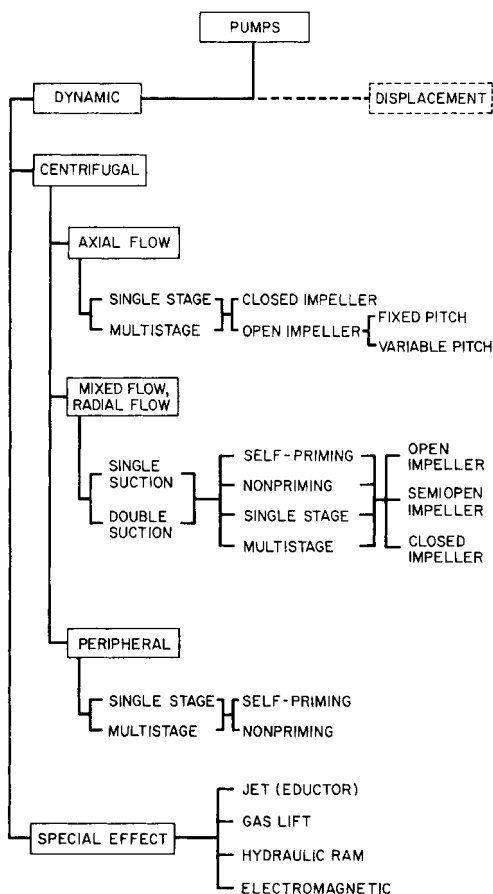

FIGURE 1 Classification of dynamic pumps

to values greater than those occurring at the discharge so subsequent velocity reduction within or beyond the pump produces a pressure increase, and (2) displacement, in which energy is periodically added by application of force to one or more movable boundaries of any desired number of enclosed, fluid-containing volumes, resulting in a direct increase in pressure up to the value required to move the fluid through valves or ports into the discharge line.

Dynamic pumps may be further subdivided into several varieties of centrifugal and other special-effect pumps. Figure 1 presents in outline form a summary of the significant classifications and subclassifications within this category.

Displacement pumps are essentially divided into reciprocating and rotary types, depending on the nature of movement of the pressure-producing members. Each of these major classifications may be further subdivided into several specific types of commercial importance, as indicated in Figure 2.

Definitions of the terms employed in Figures 1 and 2, where they are not self-evident, and illustrations and further information on classifications shown are contained in the appropriate sections of this book.

FIGURE 2 Classification of displacement pumps

OPTIMUM GEOMETRY VERSUS SPECIFIC SPEED

Optimum geometry of pump rotors is primarily influenced by the specific speed N_s or Ω_s , defined as shown in Figure 3. This parameter is one of the dimensionless groups that emerges from an analysis of the complete physical equation for pump performance. In this equation, performance quantities such as efficiency η and head ΔH (or just H) are stated to be functions of the volume flow rate Q , rotative speed N or angular speed Ω , rotor diameter D or radius r , viscosity, $NPSHA$, and a few quantities that have lesser influence. For low viscosity (high Reynolds number) and $NPSHA$ that exceeds what the pump requires (namely $NPSHR$), the performance in terms of the head coefficient $\psi = g\Delta H/(\Omega^2 r^2)$ is influenced only by the flow coefficient or "specific flow" $Q_s = Q/(\Omega r^3)$. Now, if one divides $Q_s^{1/2}$ by $\psi^{3/4}$, the rotor

FIGURE 3 Optimum geometry as a function of BEP specific speed (for single stage rotors).

radius $r (= D/2)$ drops out (which is convenient because we don't usually know it ahead of time), and we get the universal specific speed Ω_s as the major dependent variable—in terms of which the hydraulic design is optimized for maximum efficiency, as shown in Figure 3.

This optimum geometry carries with it an associated unique value of the head coefficient ψ , thereby effectively sizing the rotor. For “rotodynamic” or impeller pumps, imagining speed N and head ΔH to be constant over the N_s -range shown yields increasing optimum impeller diameter as shown. This size progression shows that the optimum head coefficient ψ decreases with increasing specific speed.

Outside the N_s range shown in Figure 3 for each type of rotor, the efficiency becomes unsatisfactory in comparison to that achievable with the configuration shown for this N_s . Rotary positive displacement machines such as vane pumps, gear pumps, and a variety of screw pump configurations are more appropriate for the lower values of N_s , the lowest N_s -values requiring reciprocating (piston or plunger) positive displacement pumps.

Regarding units for these relationships, the rotative speed N is in revolutions per second (rps) unless stated to be in rpm because the quantity of $g \Delta H$ usually has the units of length squared per second squared. The diameter D has the same length unit as the head; for example, in the rotor size equation, head in feet would imply diameter in feet. The universal specific speed Ω_s has the same value for any combination of consistent units, and similarly shaped turbine and compressor wheels have similar values of Ω_s —making it truly “universal.” Note that for the unit of time of seconds, Ω is given as radians per second $[= N(\text{rpm}) \times \pi/30]$, where radians are unitless.

SELECTION OF PUMPS

Given the variety of pumps that is evident from the foregoing system of classification, it is conceivable that an inexperienced person might well become somewhat bewildered in trying to determine the particular type to use in meeting most effectively the requirements for a given installation. Recognizing this, the editors have incorporated in Chapter 11, “Selecting and Purchasing Pumps,” a guide that provides the reader with reasonable familiarity regarding the details that must be established by or on behalf of the user in order to assure an adequate match between system and pump.

FIGURE 4 Approximate upper limit of pressure and capacity by pump class

Supplementing the information contained in Chapter 11, the sections on centrifugal, rotary, and reciprocating pumps also provide valuable insights into the capabilities and limitations of each of these classes. None of these, however, provide a concise comparison between the various types, and Figure 4 has been included here to do just that, at least for the basic criteria of pressure and capacity.

The lines plotted in Figure 4 for each of the three pump classes represent the upper limits of pressure and capacity currently available commercially throughout the world. At or close to the limits shown, only a few sources may be available, and pumps may well be specially engineered to meet performance requirements. At lower values of pressure and capacity, well within the envelopes of coverage, pumps may be available from dozens of sources as pre-engineered, or standard, products. Note also that reciprocating pumps run off the pressure scale, whereas centrifugals run off the capacity scale. For the former, some highly specialized units are obtainable at least up to 150,000 lb/in² (10,350 bar)¹ and perhaps slightly higher. For the latter, custom-engineered pumps would probably be available up to about 3,000,000 U.S. gal/min (680,000 m³/h), at least for pressures below 10 lb/in² (0.69 bar).

Given that the liquid can be handled by any of the three basic types and given conditions within the coverage areas of all three, the most economic order of consideration for a given set of conditions would generally be centrifugal, rotary, and reciprocating, in that order. In many cases, however, either the liquid may not be suitable for all three or other considerations—such as self-priming or air-handling capabilities, abrasion resistance, control requirements, or variations in flow—may preclude the use of certain pumps and limit freedom of choice. Nevertheless, it is hoped that the information in Figure 4 will be a useful adjunct to that contained elsewhere in this volume.

¹ 1 bar = 10⁵ Pa. For a discussion of bar, see "SI Units—A Commentary" in the front matter.

CENTRIFUGAL PUMPS

SECTION 2.1

CENTRIFUGAL PUMP THEORY

PAUL COOPER

INTRODUCTION

A centrifugal pump is a rotating machine in which flow and pressure are generated dynamically. The inlet is not walled off from the outlet as is the case with positive displacement pumps, whether they are reciprocating or rotary in configuration. Rather, a centrifugal pump delivers useful energy to the fluid or “pumpage” largely through velocity changes that occur as this fluid flows through the impeller and the associated fixed passageways of the pump; that is, it is a “rotodynamic” pump. All impeller pumps are rotodynamic, including those with radial-flow, mixed-flow, and axial-flow impellers: the term “centrifugal pump” tends to encompass all rotodynamic pumps.

Although the actual flow patterns within a centrifugal pump are three-dimensional and unsteady in varying degrees, it is fairly easy, on a one-dimensional, steady-flow basis, to make the connection between the basic energy transfer and performance relationships and the geometry or what is commonly termed the “hydraulic design” (more properly the “fluid dynamical design”) of impellers and stators or stationary passageways of these machines.

In fact, disciplined one-dimensional thinking and analysis enables one to deduce pump operational characteristics (for example, power and head versus flow rate) at both the optimum or design conditions and off-design conditions. This enables the designer and the user to judge whether a pump and the fluid system in which it is installed will operate smoothly or with instabilities. The user should then be able to understand the offerings of a pump manufacturer, and the designer should be able to provide a machine that optimally fits the user's requirements.

The complexities of the flow in a centrifugal pump command attention when the energy level or power input for a given size becomes relatively large. Fluid phenomena such as recirculation, cavitation, and pressure pulsations become important; “hydraulic” and mechanical interactions—involving stress, vibration, rotor dynamics, and the associated design approaches, as well as the materials used—become critical; and operational limits must be understood and respected.

NOMENCLATURE

NOTE: The units for each quantity defined are as stated in this nomenclature, unless otherwise specifically stated in the text, equations, figures, or tables.

A = area, in² (mm).

a = constant of the diffuser or volute configuration in Pfleiderer’s slip relation.

a = radius of impeller disk, ft (m), = $r_{t,2}$.

A_p = area of flow passage normal to the flow direction, ft² (m²).

b = width of an impeller or other bladed passage in the meridional plane, ft (m).

NOTE: When dealing with radial thrust, b_2 includes also the thickness of the shrouds.

C_p = specific heat of liquid being pumped, Btu/(lbm-degF); [kcal/(kg-degC)].

c or V = absolute velocity, ft/sec (m/s).

D = diameter; unless otherwise subscripted = impeller exit diameter, ft (m).

d = diameter, ft (m).

D_h = hydraulic diameter of flow passage (= $4A_p/\phi$), ft (m).

F = thrust force, lbf (N).

g = acceleration due to gravity, = 32.174 ft/sec² (9.80665 m/s²) at earth sea level.

g_o = constant in Newton’s Second Law, = 32.174 (lbm-ft)/(lbf-sec²). (There is no SI equivalent; use the dimensionless constant 1 in place of g_o in SI computations.)

$\{g_p\}$ = set of fluid properties associated with gas-handling phenomena

H = head of liquid column, ft (m) (Eq. 3); can also have the same meaning as the change in head ΔH (that is, the same meaning as “pump head”).

ΔH = change in head across pump or pump stage, also called the “pump head” or “total dynamic head” ft (m).

ΔH = the small reduction in pump head (usually 3%) in testing for NPSHR, ft (m).

H_e = $H_{i,\infty}$ = the ideal head for an infinite number of blades that produce no blockage.

H_i = ideal head [= $H + \Sigma(H_L)$], ft (m) (Eq. 15b); sometimes called the “input head.”

H_L = head loss, ft (m).

ΣH_L = all losses in the main flow passages from pump inlet to pump outlet, ft (m).

h = static enthalpy in Btu/lbm times $g_o J$, ft²/sec²; (or in kcal/kg times J , m²/s² = J/kg).

h_{se} or $NPSH$ = net positive suction head, ft (m).

ID = inner diameter.

J = the mechanical equivalent of heat, 778 ft-lbf/Btu
(4184 N-m/kcal).

ℓ = blade, vane, or passage arc length, ft (m).

M or T = torque, lbf-ft (N-m).

m = distance in streamwise direction in meridional plane (Figure 14), in or ft (m).

\dot{m} = mass flow rate, lbf-sec/ft (kg/s), $= \rho Q$.

$MCSF$ or Q_{\min} = minimum continuous stable flow, ft³/sec (m³/s).

N or n = rotative speed of the impeller, rpm.

$NPSH$ or h_{se} = net positive suction head, ft (m).

$NPSHA$ or $NPSH_A$ = available $NPSH$.

$NPSHR$ or $NPSH_R$ = required $NPSH$ to prevent significant loss ($> 3\%$) of pump Δp or to protect the pump against cavitation damage, whichever is greater.

$NPSH_{3\%}$ or $NPSH_{3\%}$ = required $NPSH$ to prevent significant loss ($> 3\%$) of pump Δp ; this is the “performance $NPSH$ ” defined in Section 2.3.1.

n_b or Z_i = number of impeller blades.

n_q = specific speed in rpm, m³/s, m units (Eq. 38b) $= N_g/51.64$ (Eq. 39c).

n_v or Z_d = number of vanes in diffuser or stator.

N_s or $N_{s(US)}$ or n_s = specific speed in rpm, gpm, ft units (Eq. 38a).

N_{ss} or S = suction specific speed in rpm, gpm, ft units (Eq. 42).

OD = outer diameter.

P = total pressure, lbf/ft² (Pa).

p = pressure, lbf/ft² [Pa ($=N/m^2$)] ($=$ “static pressure”).

Δp = pressure rise, lbf/ft² (Pa).

p_L = pressure loss, lbf/ft² (Pa).

$p_{L,i}$ = impeller pressure loss from its inlet to the point of interest, lbf/ft² (Pa).

$p_{L,i+1/L}$ = pressure loss $p_{L,i}$ in impeller plus pressure loss in inlet passage, lbf/ft² (Pa).

Σp_L = all losses in the main flow passages from pump inlet to pump outlet, lbf/ft² (Pa).

p_v or p_{vp} = vapor pressure of liquid being pumped, lbf/ft² (Pa).

P_I = power delivered to all fluid flowing through the impeller, ft-lbf/sec (kW).

P_S = shaft power, ft-lbf/sec (kW).

\wp = perimeter of flow passage cross section normal to the flow direction, ft (m).

Q = volume flow rate or, more conveniently, “flow rate” or “capacity,” ft³/sec (m³/s).

Q_{DR} = flow rate below which discharge recirculation exists, ft³/sec (m³/s).

Q_L = leakage from impeller exit to inlet, ft³/sec (m³/s).

Q_{\min} or $MCSF$ = minimum continuous stable flow rate, ft³/sec (m³/s).

Q_R = flow rate below which recirculation exists, ft³/sec (m³/s).

- Q_{SR} = flow rate below which suction recirculation exists, ft³/sec (m³/s).
- Q3D (quasi-3D) = quasi-three dimensional.
- R = radius of curvature of meridional streamline, ft (m) (Figures 13, 14, and 25).
- r = radial distance from axis of rotation, ft (m).
- r_b = radial distance from axis of rotation to center of circle defining impeller passage width, ft (m) (Figures 13 and 25).
- r_e = maximum value of r within the “eye plane.” (Figures 13 and 25).
- s = width of gap between impeller disk and adjacent casing wall, ft (m).
- $S = N_{ss}$, suction specific speed in rpm, gpm, ft units (Eq. 42).
- sp. gr. = specific gravity, namely, the ratio of liquid density to that of water at 60°F (15.6°C).
- {S} = set of flow properties associated with solids in the pumpage
- T = axial thrust, lbf (N).
- T or \mathbf{T} or M = torque, lbf-ft ($N\cdot m$).
- T = temperature, °F or °R (°C or °K).
- ΔT_c = temperature rise due to compression, °F (°C).
- t = time, sec (s).
- t = blade or vane thickness, ft (m).
- u = internal energy in Btu/lbm multiplied by $g_c J$, ft²/sec²; (or in kcal/kg times J , m²/s²).
- U = tangential speed Ωr of the point on the impeller at radius r , ft/sec (m/s).
- U_e = the value of U at the maximum radial location r_e within the “eye plane.”
- V = volume, ft³ (m³).
- V or c = absolute velocity of fluid, ft/sec (m/s).
- V_e = the average value of the meridional velocity component V_m in the eye (= Q/A_e), ft/sec (m/s).
- V_s = slip velocity (Figure 15), ft/sec (m/s).
- W or w = velocity of fluid relative to rotating impeller, ft/sec (m/s).
- W_g = the one-dimensional value of W that would exist if there were no slip.
- w_1 = throat width (Figure 21), ft (m).
- y = transformed distance along blade from trailing edge (Figure 19), in or ft (m).
- z = axial distance in polar coordinate system, ft (m).
- Z or Z_e = elevation coordinate, ft (m).
- Z_d or n_v = number of vanes in diffuser or stator.
- Z_i or n_b = number of impeller blades.
- α = angle of the absolute velocity vector from the circumferential direction.
- β = angle of the relative velocity vector or impeller blade in the plane of the velocity diagram (as seen, for example, in Figure 3) from the circumferential (tangential) direction.

- γ = fluid weight density, lbf/ft³ (N/m³) = ρg . (1N = 1 kg-m/s²).
- δ = clearance, ft (m)
- δ^* = displacement thickness of the boundary layer, ft (m).
- δ_0^* = displacement thickness of the zero-pressure-gradient boundary layer, ft (m), ($\approx 0.002 \times \ell$ for turbulent boundary layers at $\nu = 1$ cs in typical centrifugal pumps).
- ε = absolute roughness height, ft (m)
- ε_2 = fraction of impeller discharge meridional area (that is, the area normal to the velocity component $V_{m,2}$) that is *not* blocked by the thickness of the blades and the boundary layer displacement thickness on blades and on hub and shroud surfaces.
- $\varepsilon_{2,b}$ = fraction of the circumference at the exit of the impeller that is *not* blocked by the thickness of the blades and boundary layer displacement thickness on blades. (See computation in Table 4.)
- $\eta = \eta_p$ = pump efficiency; or a component efficiency (different subscript, Eqs. 8–11).
- θ = rotational polar coordinate or central angle about the impeller axis, radians.

NOTE: In a polar-coordinate description of impeller blades or stationary vanes, θ becomes the construction angle and is usually regarded as positive in the direction of the blade development from inlet to exit of the impeller or other blade row.

- μ = slip factor = V_s/U_2 ($= 1 - h_0$, where h_0 is the slip factor as defined by Busemann¹⁸.)
- μ = absolute viscosity, lbf-sec/ft² (Pa-s or N-s/m²); often quoted in centipoises, abbreviated to “cp” (1 cp = 0.001 Pa-s). [μ in cp] = sp. gr. \times (ν in cs).]
- ν = kinematic viscosity ($= \mu/\rho$), ft²/sec (m²/s); often quoted in centistokes, abbreviated to “cs” (1 cs = 1 mm²/s). [ν in cs] = (μ in cp)/sp. gr.
- ρ = fluid mass density, lbf-sec²/ft⁴ (kg/m³), = γ/g .
- σ = solidity (Eq. 53).
- σ = Thoma's cavitation parameter = h_{s0}/H .
- T** or T or M = torque, lbf-ft (N-m).
- ϕ = flow coefficient.
- $\phi_e = V_e/U_e$ = impeller inlet or eye flow coefficient.
- ϕ_i (or $\phi_{i,2}$) = impeller exit flow coefficient = $V_{m,2}/U_2$ (Figure 12).
- ψ = head coefficient (Figure 12); stream function (Figure 14).
- ψ_i = ideal head coefficient [$= \psi_{i,2} = V_{\theta,2}/U_2$ for zero inlet swirl ($V_{\theta,1} = 0$)].
- $\psi_{i,2} = V_{\theta,2}/U_2$ [$= \psi_i$ for zero inlet swirl ($V_{\theta,1} = 0$)].
- Ω = angular speed of the impeller in radians per second (1/s) = $N\pi/30$.
- Ω_s = universal specific speed (unitless) (Eq. 37) = $N_s/2733$ (Eq. 38a) = $n_q/52.92$ (Eq. 38b).
- Ω_{ss} = universal suction specific speed (unitless) (Eq. 41) = $N_{ss}/2733$ (Eq. 42).
- {2-ph} = set of fluid properties associated with vaporization

Subscripts

- b = impeller blade.
- D = drag due to disk friction, bearings, and seals.
- DF = disk friction.
- d = discharge flange or exit (ex) of the pump.
- e = at the “eye” of the impeller. The “eye” is the throat (minimum-diameter point) at the entrance into the impeller and is the area defined by the “eye plane,” which is normal to the axis of rotation. “ e ” can refer more specifically to the shroud or maximum-diameter point within the eye, as with r_e (Figure 13) or U_e . The inlet tips of the impeller blades are generally at or near this location.
- ex = exit of diffuser or the discharge flange or port of the pump (d).
- f = the direction of the flow.
- h = hub.
- i = inner limit of region or gap (Tables 4 and 5)
- i (or ideal) = ideal.
- i (or imp) = impeller.
- in (or s) = pump inlet flange or port.
- I/L = inlet passage; that is, the passage from the pump inlet flange or port to the impeller.
- I = input to fluid.
- L = losses.
- m = “mechanical” (pertaining to efficiency, Eq. 9).
- m = component of velocity in the meridional plane (that is, the axial-radial plane containing the axis of rotation).
- mean = the 50% or rms meridional streamline.
- n = normal or BEP value.
- o = outer limit of region or gap (Tables 4 and 5).
- out = pump outlet flange or port.
- p = pressure side of blade or passage.
- R = value of r at the impeller ring clearance.
- S = shaft.
- s (or in) = suction flange or inlet of the pump.
- SE = shockless entry (that is, inlet velocity vector aligned with blade camber line).
- s/o = shut-off or zero flow rate Q .
- r = in the radial direction.
- rms = the 50% or mean meridional streamline.
- s = shaft.
- s = suction side of blade or passage.
- s = same meaning as sh and t .
- sh = shroud (also at the eye plane at inlet—and in general “ t ” at outlet).
- stg = stage.
- T = entry throat of volute or diffuser.

- t = the tip or maximum radial position of the impeller blades at inlet or outlet (same meaning as s and sh).
 t = tongue or cutwater.
 u (see θ , below).
 v = volumetric (pertaining to efficiency, Eq. 11).
 v = volute.
 z = in the axial direction.
 θ or u = component of velocity in the circumferential direction (that is, the tangential direction in the polar view that is perpendicular to the axis of rotation).
 1 = impeller inlet at the blade leading edge—at the mean unless further defined.
 2 = impeller outlet at the blade trailing edge—at the mean unless further defined.
 3 = volute base circle or entrance to diffuser.
 ∞ = for an infinite number of blades that also produce zero blockage of the flow.

Superscripts

- $-$ = average value

ENERGY TRANSFER

Hydraulics or fluid dynamics has the primary influence on the geometry of a rotodynamic pump stage—of all the engineering disciplines involved in the design of the machine. It is basic to the energy transfer or pumping process. Staging is also influenced by the other disciplines, especially in high-energy pumps. The basic energy transfer relationships need to be thoroughly understood to achieve a credible design and to understand the operation of these machines. Action of the mechanical input shaft power to effect an increase in the of energy of the pumpage is governed by the first law of thermodynamics. Realization of that energy in terms of pump pressure rise or head involves losses and the second law of thermodynamics.

The First Law of Thermodynamics Fluid flow, whether liquid or gas, through a centrifugal pump is essentially adiabatic, heat transfer being negligible in comparison to the other forms of energy involved in the energy transfer process. (Yet, even if the process were not adiabatic, the density of a liquid is only weakly dependent on temperature.) Further, while the delivery of energy to fluid by rotating blades is inherently unsteady (varying pressure from blade to blade as viewed in an absolute reference frame), the flow across the boundaries of a control volume surrounding the pump is essentially steady, and the first law of thermodynamics for the pump can be expressed in the form of the adiabatic steady-flow energy equation (Eq. 1) as follows:

$$P_S = \dot{m} \left[\left(h + \frac{V^2}{2} + gZ_e \right)_{\text{out}} - \left(h + \frac{V^2}{2} + gZ_e \right)_{\text{in}} \right]$$

where
$$h = u + \frac{p}{\rho} \quad (1)$$

FIGURE 1 Energy transfer in a centrifugal pump

Here, shaft power P_s is transformed into fluid power, which is the mass flow rate \dot{m} times the change in the total enthalpy (which includes static enthalpy, velocity energy per unit mass, and potential energy due to elevation in a gravitational field that produces acceleration at rate g) from inlet to outlet of the control volume (Figure 1).

When dealing with essentially incompressible liquids, the shaft power is commonly expressed in terms of “head” and mass flow rate, as in Eq. 2:

$$\frac{P_s}{\dot{m}} = g\Delta H + \Delta u \quad (2)$$

where

$$H = \frac{p}{\rho g} + \frac{V^2}{2g} + Z_e \quad (3)$$

The change in H is called the “head” ΔH of the pump; and, because H (Eq. 3) includes the velocity head $V^2/2g$ and the elevation head Z_e at the point of interest, ΔH is often called the “total dynamic head.” ΔH is often abbreviated to simply “ H ” and is the increase in height of a column of liquid that the pump would create if the static pressure head $p/\rho g$ and the velocity head $V^2/2g$ were converted without loss into elevation head Z_e at their respective locations at the inlet to and outlet from the control volume; that is, both upstream and downstream of the pump.

The Second Law of Thermodynamics: Losses and Efficiency As can be seen from Eq. 2, not all of the mechanical input energy per unit mass (that is, the shaft power per unit of mass flow rate) ends up as useful pump output energy per unit mass $g\Delta H$. Rather, losses produce an internal energy increase Δu (accompanied by a temperature increase) in addition to that due to any heat transfer into the control volume. This fact is due to the second law of thermodynamics and is expressed for pumps in Eq 4:

$$g\Delta H < \frac{P_s}{\dot{m}} \quad \text{or} \quad \eta < 1 \quad (4)$$

FIGURE 2 Determining component efficiencies. (This is a meridional view.)

where

$$\dot{m} = \rho Q$$

The losses in the pump are quantified by the overall efficiency η , which must be less than unity and is expressed in Eq. 5:

$$\eta = \frac{g\Delta H\dot{m}}{P_s} = \text{Overall Pump Efficiency} \quad (5)$$

It should be pointed out here that real liquids undergo some compression—which is accompanied by a reversible increase in the temperature ΔT_c of the liquid—called the “heat of compression.” This portion of the actual total temperature rise ΔT is in addition to that arising from losses and must therefore be taken into account when determining efficiency from measurements of the temperature rise of the pumpage.¹ See the discussion on this subject in Section 2.3.1.

To pinpoint the losses, it is convenient to deal with them in terms of “component efficiencies.” For the typical shrouded- or closed-impeller pump shown in Figure 2, Eq. 5 can be rewritten as follows:

$$\eta = \frac{P_i}{P_s} \times \frac{g\Delta H(\dot{m} + \dot{m}_L)}{P_i} \times \frac{\dot{m}}{\dot{m} + \dot{m}_L} \quad (6)$$

Noting that

$$P_i = g\Delta H_i(\dot{m} + \dot{m}_L) \quad (7)$$

and

$$\dot{m} = \rho Q$$

$$H_i = \text{Ideal Head}$$

one may rewrite Eq. 6 as follows:

$$\eta = \frac{P_I}{P_S} \times \frac{\Delta H}{\Delta H_i} \times \frac{Q}{Q + Q_L} = \eta_m \times \eta_{HY} \times \eta_v \quad (8)$$

where

$$\left. \begin{array}{l} \text{"Mechanical"} \\ \text{Efficiency} \end{array} \right\} \eta_m = \frac{P_I}{P_S} = \frac{P_S - P_D}{P_S} \quad (9)$$

$$\left. \begin{array}{l} \text{Hydraulic} \\ \text{Efficiency} \end{array} \right\} \eta_{HY} = \frac{\Delta H}{\Delta H_i} = \frac{\Delta H_i - \Sigma H_L}{\Delta H_i} \quad (10)$$

$$\left. \begin{array}{l} \text{Volumetric} \\ \text{Efficiency} \end{array} \right\} \eta_v = \frac{Q}{Q + Q_L} \quad (11)$$

Approximate formulas for the three component efficiencies of Eq. 8 will be given further on. Their product yields the overall pump efficiency as defined in Eq. 5, and reflects the following division of the pump losses:

- a. External drags on the rotating element due to i) bearings, ii) seals, and iii) fluid friction on the outside surfaces of the impeller shrouds—called “disk friction”; the total being $P_D = P_S - P_I$. Generally, the major component of P_D is the disk friction, and the “mechanical efficiency” is that portion of the shaft power that is delivered to the fluid flowing through the impeller passages.
- b. Hydraulic losses in the main flow passages of the pump; namely, inlet branch, impeller, diffuser or volute, return passages in multistage pumps, and outlet branch. The energy loss per unit mass is $g\Sigma H_L = g(H_i - \Delta H)$, the ratio of output head ΔH to the input head H_i being the hydraulic efficiency. This is the major focus of the designer for typical centrifugal pump geometries (which are associated with normal “specific speeds”—to be defined later). The other two component efficiencies are then quite high and of relatively little consequence.
- c. External leakages totaling Q_L leaking past the impeller and back into the inlet eye. This leakage has received its share of the full amount of power $P_I = \rho g \Delta H_i (Q + Q_L)$ delivered to all the fluid $(Q + Q_L)$ passing through the impeller. This leakage power is $P_L = \rho g \Delta H_i Q_L$, which is lost as this fluid leaks back to the impeller inlet. The remaining fluid input power is thus $(P_I - P_L) = \rho g \Delta H_i Q$, the ratio of this power to the total (P_I) being the volumetric efficiency.

There are exceptions to this convenient model for dividing up pump losses. The main exception is that if the pump has an open impeller, that is, one without either or both shrouds, that portion of the total leakage Q_L disappears. The leakage now occurs across the blade tips and affects the main flow passage hydraulic losses. The volumetric efficiency is now higher, but the hydraulic efficiency is lower. In that case disk friction is still present, as the impeller still has to drag fluid along the adjacent stationary wall(s). Another exception—for closed impellers—is that disk friction is fundamentally an inefficient pumping action, the fluid being flung radially outward²; and this can result in a slight increase in pump head if the fluid on the outside of an impeller shroud or disk is pumped into the main flow downstream of the impeller.

VELOCITY DIAGRAMS AND HEAD GENERATION

The mechanism of the transfer of shaft torque (or power) to the fluid flowing within the impeller is fundamentally dynamic; that is, it is connected with changes in fluid velocity. This requires the introduction of Newton's second law, which when combined with the first

FIGURE 3 Impeller velocity diagrams (1 = inlet; 2 = outlet)

law of thermodynamics, yields Euler's Pump Equation. Fluid velocities at inlet and exit of the impeller are fundamental to this development. Fluid flowing along the blades of an impeller rotating at angular velocity Ω and viewed in the rotating reference frame of that impeller has relative velocity W . Vectorially adding W to impeller blade speed $U = \Omega r$ yields the absolute velocity V , as shown in the velocity diagrams of Figure 3.

Newton's Second Law for Moments of Forces and Euler's Pump Equation Relating impeller torque \mathbf{T} to fluid angular momentum per unit mass rV_θ is the convenient way of applying Newton's second law to centrifugal pumps. This is stated as follows for the control volume \mathbf{V} that contains the pump impeller (Eq. 12):

$$\Sigma \mathbf{T} = \iint \mathbf{V} \cdot \frac{\partial(\rho r V_\theta)}{\partial t} / d\mathbf{V} + \iint \rho r V_\theta dQ \quad (12)$$

where $\Sigma \mathbf{T} = \mathbf{T}_s - \mathbf{T}_D$ is the summation of torques acting on the impeller; namely, the net torque \mathbf{T}_I acting on the fluid flowing through it. The volume integral (first term on the right side) of Eq. 12 is the unsteady term, which is zero for steady operation. It comes into play during changing or transient conditions, such as start up and shutdown; that is, when the angular momentum per unit volume $\rho r V_\theta$ is changing with time within the impeller volume \mathbf{V} .

The surface integral (second term on the right hand side) of Eq. 12 is the one that pump designers and users are mainly concerned with. Its integration over the exterior surface of the control volume \mathbf{V} is effectively accomplished for most impellers by combining one-dimensional results from inlet to outlet on each of several stream surfaces—imagined to be nested surfaces of revolution bounded by the hub and shroud stream surfaces (indicated in Figure 2). Insight into the power of this term can be gained by taking the mean value of the integrand in terms of the velocities on a representative stream surface; that is, essentially the surface of revolution lying at an appropriate mean location between hub and shroud. Each of the two velocity diagrams of Figure 3 lies in a plane tangent to this mean stream surface. For flow through an impeller, the torque delivered to the fluid is therefore given by the following relationship involving these average quantities:

$$\mathbf{T}_I = (\dot{m} + \dot{m}_L) \times (r_2 V_{\theta,2} - r_1 V_{\theta,1}) \quad (13)$$

or $\times \Omega$:

$$P_I = (\dot{m} + \dot{m}_L) \times (U_2 V_{\theta,2} - U_1 V_{\theta,1}) \quad (14)$$

Eq. 13 says that the torque is equal to the mass flow rate times the change of angular momentum per unit mass $\Delta(rV_\theta)$. This becomes the “power” statement of Eq. 14 when both sides are multiplied by Ω . Following the statement of the second law of thermodynamics in Eq. 4, we now can similarly say that $g\Delta H$ must be less than the power input to the fluid per unit of mass flow rate, namely $\Delta(UV_\theta)$ from Eq. 14. So, we now arrive at Euler’s Pump Equation—expressed three different ways as follows:

$$g\Delta H < \Delta(UV_\theta) \quad (15a)$$

$$g\Delta H_i = \Delta(UV_\theta) \quad (15b)$$

or

$$g\Delta H = \eta_{HY}\Delta(UV_\theta) \quad (15c)$$

The inequality (Eq. 15a) is quantified by Eq. 15b, which follows in view of Eq. 7. Eq. 15c then follows from the definition of hydraulic efficiency (Eq. 10). Euler’s Pump Equation makes one of the most profound statements in the field of engineering, because it determines the major geometrical features of the design of a rotodynamic machine. By reversing the inequality in Eq. 15a, the same principle applies to turbines; hence, the more encompassing title, “Euler’s Pump and Turbine Equation.”

So, to design or analyze a pump, one needs to a) obtain the velocity diagrams that will produce the ideal head at the design flow rate and b) determine how the shape of these diagrams affects the hydraulic efficiency η_{HY} , so as to obtain the desired pump stage head. Step (a) for a given pump is a simple one-dimensional exercise that utilizes the principles of continuity and kinematics (Eqs. 16 and 17) to construct the velocity diagrams for a given total impeller volume flow rate Q and pump rotative speed (Ω or N):

$$\text{Continuity:} \quad Q = 2\pi r b V_m \quad (16)$$

where $W = V_m / \sin \beta_f$

$$\text{Kinematics:} \quad V_\theta = U - W \cos \beta_f \quad (17)$$

Step (b) is in essence the evaluation of the hydraulic losses ΣH_L in Eq. 10, which depend mainly on the relative and absolute velocities, the associated flow passage dimensions, and incidence angles. Eq. 15c then gives the head that the pump stage will generate. Performing steps (a) and (b) at several other flow rates at the same speed enables one to develop the pump performance characteristics.

STATIC PRESSURE GENERATION

The Extended Bernoulli Equation To estimate the losses, it is convenient first to investigate the static pressure and velocity head portions of the total head. Eq. 15c can be written in terms of the total pressure P , which equals $\rho g H$. Similarly, we may speak of hydraulic losses as losses of static pressure Σp_L , which equals $\rho g \Sigma H_L$; so

$$P = P_{in} + \rho(UV_\theta - U_1 V_{\theta,1}) - \Sigma p_L \quad (18)$$

where, from Eq. 3, the static, dynamic and potential energy components of the total pressure are brought into evidence:

FIGURE 4 Velocity triangle and flow within impeller passageway

$$P = p + \frac{1}{2} \rho V^2 + \rho g Z_e = \rho g H \quad (19)$$

Eq. 18 is the turbomachine form of the “extended Bernoulli equation,” which states that along a streamline the total pressure P —also known as the Bernoulli constant and defined in Eq. 19—is a) decreased by losses and b) increased by energy addition that occurs along the streamline.

Centrifugal and Diffusion Effects in Impellers Changes in potential energy across a pump stage are small; so the static pressure rise is found essentially from subtracting the dynamic (velocity) pressure change from the total pressure change. Within the impeller, the static pressure in turn arises from a) centrifugal and b) passage diffusion effects.

Fluid in the impeller passage of Figure 4b flows from low to high radius r or blade speed U , often also experiencing a decrease in passage relative velocity W . The geometry of the velocity diagram (Figure 4a) leads to the following combination of Eqs. 18 and 19 applied across the impeller:

$$\Delta \left(p + \frac{1}{2} \rho V_m^2 + \frac{1}{2} \rho V_\theta^2 \right) = \Delta [\rho U \times (U - W \cos \beta)] - p_{L,i} - \Delta(\rho g Z_e) \quad (20)$$

and, because $V_m = W$, this simplifies to the following form of the extended Bernoulli equation, which applies along a streamline from the inlet of the impeller:

$$\underbrace{p - p_1}_{\text{Static Pressure Change}} = \frac{1}{2} \rho \underbrace{(U^2 - U_1^2)}_{\text{Centrifugal Effect}} + \underbrace{W_1^2 - W^2}_{\text{Passage Diffusion}} - \underbrace{p_{L,i}}_{\text{Losses:}} - \rho g(Z_e - Z_{e,1})$$

Incidence

Mixing

}

($\rho \Delta u$)

(21)

Here, the U -increase corresponds to the centrifugal contribution to the static pressure rise, and the W -decrease to the diffusion contribution. There is no U -change along an axial streamline in an axial-flow impeller or propeller; so, static pressure rise is due only to diffusion. Radial-flow impellers, on the other hand, often have little or no net W -change, the centrifugal effect being paramount. [A study of the velocity diagrams of Figure 3 suggests that such impellers possess a high “degree of reaction.” The degree of reaction is defined as that fraction of the total energy addition within the impeller (Eq. 15b) that does *not* include the change in absolute velocity energy, $\Delta(V^2/2)$. This fraction is, therefore, the sum

of the static pressure energy change, that due to elevation change, and the energy losses in the impeller, as can be seen from Eqs. 18 and 19.]

Collector Static Pressure Rise, Inlet Nozzle Drop A similar form of Eq. 21 applies in the stationary flow elements, where W is also the absolute velocity V and blade speed U is zero. (This would be a more recognizable form of the extended Bernoulli equation, wherein only losses modify the Bernoulli constant.³⁾ A further static pressure increase occurs in the stationary collection system downstream of the impeller (with the attendant losses); namely, in the stationary volute or diffuser. This static rise is generally about a third of that in the impeller, and it is due only to diffusion, that is, the decrease in velocity in that passage. To complete the picture, there is often an increase in the comparatively small velocity in the approach passageway or nozzle or suction branch from the pump inlet port or flange to the impeller eye or blade leading edge. This is accompanied by an attendant small pressure drop.

Internal Static Pressure Distribution If the fluid enters the pump from a stagnant pool, the total pressure at the impeller eye P_1 will be very nearly the static pressure of the upstream pool (plus the pressure equivalent of the elevation of the pool above the eye). This is one reason why the local static pressure p within the pump is often referenced to P_1 , as indicated in the following form of Eq. 21:

$$p - P_1 = \frac{1}{2} \rho (U^2 - W^2) - p_{L,i} - \rho g Z_e - \rho U_1 V_{\theta,1} \quad (22)$$

where

$$P_1 = p_1 + \rho \frac{V_1^2}{2} + \rho g Z_{e,1} \quad (23)$$

Figure 5 is an illustration of the internal static pressure development. The difference between P_1 and p_1 is due to the impeller inlet absolute velocity head or dynamic pressure $\rho V_1^2/2$, a much larger difference existing at the impeller exit, namely $\rho V_2^2/2$. Losses in the collector result in the pump or stage outlet total pressure P_{out} being less than P_2 , the rise in total pressure ΔP_{pump} from port to port being $P_{out} - P_{in}$. In the figure, P_{in} is very nearly the same as P_1 , the inlet passage loss being comparatively small for most pumps.

NET POSITIVE SUCTION HEAD

Local reduction of the static pressure p to the vapor pressure p_v of the liquid causes vaporization of the liquid and cavitation. Internal pressure drops are due to a) impeller inlet velocity head and inlet passage loss and b) blade loading and loss within the impeller. In order to prevent a substantial decrease of impeller pressure rise, the sum of these pressure drops should not exceed the difference between P_{in} and p_v , the head equivalent of which is called "net positive suction head" or *NPSH*:

$$\frac{P_{in} - p_v}{\rho g} \equiv NPSH \Rightarrow P_{in} = \rho g NPSH + p_v \quad (24)$$

Insufficient *NPSH* leads to cavitation and loss of pump pressure rise. That is because the impeller can become filled with vapor, in which case the density ρ of the fluid within the impeller is then reduced by orders of magnitude. This in turn, as can be seen in Eqs. 18–22, results in essentially zero pump pressure rise; that is, total loss of pump performance.

Eq. 24 substituted into Eq. 22 yields the local static pressure above vapor pressure in terms of the *NPSH*:

FIGURE 5 Pump stage internal pressure development. Total pressure rise $\Delta P = \rho g \Delta H$.

$$p - p_v = \rho g NPSH + \frac{1}{2} \rho (U^2 - W^2) \quad (25)$$

$$- p_{L,i+1/L} - \rho g Z_e - \rho U_1 V_{\theta,1}$$

This, together with the foregoing pressure drops, which occur in the inlet region of the pump, is illustrated in Figure 5. The figure contains three plots of p along the representative streamline from 1 to 2, m being distance along this line in the meridional plane. These plots are for the suction side or trailing face of an impeller blade, the pressure side or driving face, and the average or mid-passage position. The middle or average pressure plot is readily described by Eq. 25 in terms of the local average W -distribution. The local blade-to-blade static pressure difference $p_p - p_s$ arises from the torque exerted on a strip of fluid between the blades and approximated here via blade-to-blade average velocity components in Newton's Second Law for Moments of Forces:

$$r(p_p - p_s)b dm = \rho V_m b r \cdot \Delta \theta \cdot d(r V_\theta) \quad (26)$$

$$p_p - p_s = \frac{2\pi}{n_b} \frac{\rho V_m}{\Omega} \frac{d(U V_\theta)}{dm}$$

where, for ease of illustration, the blade-to-blade polar angle difference $\Delta\theta$ is taken equal to $2\pi/n_b$, the actual value of $\Delta\theta$ being slightly less than this due to the thickness of the blades. Thus, for example, too small a number of blades n_b results in a larger value of $p_p - p_s$ and a lower minimum static pressure in the inlet region of the impeller.

The density reduction in a cavitating impeller is difficult to predict analytically; therefore, empirical relationships for acceptable levels of *NPSH* have been developed and will be presented further on, as guidelines for design and performance prediction are developed.

PERFORMANCE CHARACTERISTIC CURVES

Velocity diagrams and ideal head-rise vary with flow rate Q as illustrated in Figure 6 for the typical case of constant rotative speed N or angular speed Ω . Flow patterns in Figure 6b correspond to points on the characteristic curves of Figure 6a. The inlet velocity diagrams (just upstream of the impeller) are shown there for high and low flow rate—with zero swirl being delivered by the inlet passageway to the impeller; that is, $V_{\theta,1} = 0$. The outlet velocity diagrams on Figure 6a are found one-dimensionally, the magnitude of the exit relative velocity vector W_2 varying directly with Q and its direction being nearly tangent to the impeller blade. From these diagrams are found the absolute velocity vector V_2 and its circumferential component $V_{\theta,2}$. Because blade speed U_2 is constant, the resulting plot of the ideal head $\Delta H_i = U_2 V_{\theta,2}/g$ (from Eq. 15b) is a straight line, rising to the point U_2^2/g at zero- Q or “shut-off head.” This is twice the impeller OD tip speed head $U_2^2/2g$. The right-most velocity diagram in Figure 6a has zero $V_{\theta,2}$; however, the maximum or “runout” flow rate happens at lower Q than this. That is because the actual head H is less than ΔH_i due to losses (as seen in Eq. 10), and $\Delta H = 0$ at runout—where overall pump efficiency (Eq. 8) is also zero.

This one-dimensional analysis works well in the vicinity of the best efficiency point (b.e.p. or BEP) and at higher Q because the fluid flows smoothly through the impeller pas-

FIGURE 6A and B Characteristic performance curves of a pump stage, related to velocity diagrams

sages as illustrated in Figure 6b for “high Q .” However, it fails at “low Q ,” where recirculating flow develops—indicated by a substantial one-dimensional deceleration or reduction in the fluid velocity relative to those passages—that is, $W_2 \ll W_1$. This is analogous to a diffuser with side walls that diverge too much: the main fluid stream separates from one or both walls and flows along in a narrow portion of the passage in a jet—the rest of the passage being occupied with eddying fluid that can recirculate out of the impeller inlet and exit. Consequently, the real outlet velocity diagram at low Q is the one with the dashed lines and the smaller value of $V_{\theta, 2}$, rather than the solid-lined, one-dimensional diagram superimposed on it. This in turn reduces the ideal head at the low- Q point of the curves.

To complicate matters further at low Q , one-dimensional application of this “corrected” outlet velocity diagram via Eq. 14 would produce a pump power consumption curve that passes through the origin of Figure 6a. Such a result (assuming negligible external drag power P_D), is known not to occur in a real pump. Rather, superimposed on the jet flow pattern just described is recirculating fluid that leaves the impeller, gives up its angular momentum to its surroundings, and re-enters the impeller to be re-energized.

In other words, the one-dimensional simplifications mentioned after Eq. 12 do not hold at low Q ; rather, there is an added “recirculation power,” which is the UV_r -change experienced by the recirculating fluid integrated over each element of re-entering mass flow rate⁴. The complexity of this recirculation destroys one’s ability to interpret pump performance under such conditions by means of velocity diagrams. Instead, a transition is made from empirical correlations for head and power at “shutoff” or zero net flow rate to the high- Q , one-dimensional analysis, enabling one to arrive at the complete set of characteristic curves for efficiency, power, and head illustrated in Figure 6a. In fact, impeller pressure-rise at shutoff is very nearly what would be expected due to the centrifugal effect of the fluid rotating as a solid body, namely $\rho U_2^2/2$. The recirculating flow patterns seem to be merely superimposed with little effect on impeller pressure-rise. This recirculation, on the other hand, does produce some additional shutoff pressure rise in the collecting and diffusing passages downstream of the impeller.

SCALING AND SIMILITUDE

When a set of characteristic curves for a given pump stage is known, that machine can be used as a model to satisfy similar conditions of service at higher speed and a different size. Scaling a given geometry to a new size means multiplying every linear dimension of the model by the scale factor, including all clearances and surface roughness elements. The performance of the model is then scaled to correspond to the scaled-up model by requiring similar velocity diagrams (often called “velocity triangles”) and assuming that the influences of fluid viscosity and vaporization are negligible. The proportions associated with Eqs. 27, 29, and 32 illustrate this. The blade velocity U (Eq. 30) varies directly with rotative speed N or angular speed Ω —and directly with size, as expressed by the radius r . For the velocity V (or W) to be in proportion to U , the flow rate Q must therefore vary as Ωr^3 ; hence, the “specific flow” Q_s must be constant (Eq. 28). Further, as the head is the product of two velocities, it must vary as $\Omega^2 r^2$; hence, the head coefficient ψ must be constant (Eq. 31). Finally, as power is the product of pressure-rise and flow rate, shaft power P_s must vary as $\rho \Omega^3 r^5$; hence, the power coefficient must be constant.

$$Q = AV \quad \begin{cases} A \propto r^2 & \propto D^2 \\ V \propto \Omega r_2 & \propto ND \end{cases}$$

$$\Rightarrow Q \propto ND^3 \quad \text{or} \quad \Omega r_2^3 \quad (27)$$

$$\text{and} \quad \frac{Q}{\Omega r_2^3} = \text{Constant} = Q_s \quad (28)$$

At above Q ,

$\eta = \text{Constant}$, and

$$\begin{aligned} g\Delta H &= \eta_{HY}\Delta(UV_\theta) \\ &\Rightarrow \Delta H \propto N^2 D^2 \end{aligned} \quad (29)$$

$$U = \Omega r \quad (30)$$

and

$$\psi = \frac{g\Delta H}{U_2^2} = \text{constant} \quad (31)$$

$$\begin{aligned} P_S &= \frac{\rho Q g \Delta H}{\eta} \\ &\Rightarrow P_S \propto \rho N^3 D^5 \end{aligned} \quad (32)$$

and

$$\hat{P}_S = \frac{P_S}{\rho \Omega^3 r_2^5} = \text{constant} \quad (33)$$

Figure 7a is the result of following these similarity rules for a given pump that undergoes a change in speed from full speed to half speed without a change in size. The similar Q at half speed for a given Q at full speed is half that at full speed. At each such half-speed Q -value, the head ΔH is accordingly one-fourth of its full-speed value and the efficiency η is unchanged. One can avoid replotting the characteristic curves in this manner for every change in speed (and size) by expressing them nondimensionally in terms of Q_s , ψ , η , and \hat{P}_s . They then all collapse on one another as illustrated in Figure 7b. Note that a change in pump geometry or shape of the hydraulic passageways destroys this similitude and necessarily produces a new set of curves—shaped differently but similar to each other.

Similitude enables the engineer to work from a single dimensionless set of performance curves for a given pump model. This is a practical but special case of the more general statement that pump performance as represented by efficiency, head, and power, is more generally expressed in terms of the complete physical equation as follows:

$$\eta, \Delta H, P_S = \text{fct's. } (Q, r_2, \Omega, \rho, \nu, NPSH, \{2-ph\}, \{g_p\}, \{S\}, \{\ell_i\}) \quad (34)$$

where $\{\ell_i\}$ is the infinite set of lengths that defines the pump stage geometry. A common group of these lengths is illustrated in Figure 8. Dimensionlessly, Eq. 34 becomes

$$\eta, \psi, \hat{P}_S = \text{fct's. } (Q_s, R_e, \tau_2, \{2-\Phi\}, \{\Gamma_p\}, \{\Sigma\}, \{G_i\}) \quad (35)$$

where the dimensionless quantities containing flow rate, viscosity and $NPSH$ are respectively defined as follows:

$$\begin{aligned} \text{where} \quad Q_s &= \frac{Q}{\Omega r_2^3} & R_e &= \frac{\Omega r_2^2}{\nu} & \tau_2 &= \frac{2gNPSH}{\Omega^2 r_2^2} \\ \text{Specific Flow} & & \text{Machine Reynolds Number} & & \text{Cavitation Coefficient} & \end{aligned} \quad (36)$$

and

- $\{G_i\} = \{\ell_i/r\}$ defines the dimensionless geometry or shape.
- $\{2-\Phi\}$ = the dimensionless quantities arising from the set of fluid, thermal, vaporization, and heat transfer properties $\{2-ph\}$ that influence the flow of two-phase vapor and liquid. These quantities come into play when the $NPSH$ is low enough for such flow to be extensive enough to influence pump performance.

FIGURE 7 Similar performance curves: a) dimensional; b) dimensionless

- $\{\Sigma\}$ = the dimensionless quantities arising from the set of properties associated with entrained solids and emulsifying fluids that affect the performance of slurry pumps and emulsion pumps.

SPECIFIC SPEED AND OPTIMUM GEOMETRY

The hydraulic geometry or shape of a pump stage can in principle be chosen for given values of the other independent variables in Eqs. 34 or 35 to optimize the resulting performance; for example, to maximize the best efficiency η_{BEP} under certain conditions on the head and power. Two such conditions that are common are a) no positive slope is allowed anywhere along the ΔH -vs.- Q curve of Figure 7 (called the “no drooping nor dip” condition) and b) the maximum power consumption must occur at the BEP (often called the “non-overloading” condition). A fundamental and generally typical pumping situation involves a) negligible influence of viscosity, (that is, high Reynolds number) b) the absence of two-phase fluid effects, (that is, the existence of sufficient *NPSH* or τ) and c) the absence of solid particles and emulsion-related substances in the fluid. In this situation, Eq. 35 has one remaining significant independent variable; namely, the specific flow Q_s , which in the definitions of Eq. 36 contains the volume flow rate Q , the pump speed Ω , and the characteristic radius r_2 . Most users don't know the

FIGURE 8 Defining the geometry of a pump stage

size of the pump stage a priori; so, r_2 is eliminated by replacing Q_s in Eq. 35 with a new quantity that is the result of dividing the square root of Q_s by the $3/4$ -power of the head coefficient ψ . Thus, from the definitions just given of Q_s and ψ , one arrives at the *specific speed* Ω_s as the independent variable in terms of which the geometry is optimized³:

$$\Omega_s = \frac{\Omega \sqrt{Q}}{(g\Delta H)^{3/4}} = \frac{\sqrt{Q_s}}{\psi^{3/4}} \quad (37)$$

For convenience, specific speed is usually expressed in terms of the conventional quantities N , Q , and ΔH that correspond to the factors in Eq. 37, which quantities are expressed in the units commonly used commercially. For example, forms found in the United States and in Europe and the relationship of these to the truly unitless “universal specific speed” Ω_s defined in Eq. 37 are as follows:

$$\Omega_s = \frac{N(\text{rpm}) \sqrt{Q(\text{USgpm})} / [\Delta H(\text{ft})]^{3/4}}{2733.016} = \frac{N_{s,(\text{U.S.})}}{2733.016} \quad (38a)$$

$$\Omega_s = \frac{N(\text{rpm}) \sqrt{Q(\text{m}^3/\text{s})} / [\Delta H(\text{m})]^{3/4}}{52.919} = \frac{n_q}{52.919} \quad (38b)$$

Thus,

$$n_q(\text{m}^3/\text{s}, \text{m}) = N_s(\text{USgpm}, \text{ft})/51.64 \quad (38c)$$

FIGURE 9 Optimum geometry as a function of BEP specific speed (for single-stage rotors)

Rotor Shape as a Function of Specific Speed Optimization of pump hydraulic geometry in terms of the BEP specific speed has taken place empirically and analytically throughout the history of pump development. An approximate illustration of the results of this process for pump rotors or impellers is shown in Figure 9. Not only does the geometry emerge from the optimization process but also the head, flow, and power coefficients for each shape as well. Approximate values for the optimum BEP head coefficient ψ are shown on the figure. The actual rotor diameter can then be deduced as noted—from the ψ -definition of Eq. 31. The relationship among the various rotors is illustrated in the figure—assuming that they all have the same speed and head; that is, as one moves along the abscissa or specific speed axis of Figure 9, only the flow rate is changing as far as the illustrations of the rotors are concerned. As would be expected, therefore, high-specific-speed impellers need to have large passages relative to their overall diameter. This is powerfully illustrated if one contrasts the propeller (high- Ω_s) with the low- Ω_s centrifugal impeller.

At the lower end of the specific speed range shown in Figure 9, rotodynamic pumps (that is, centrifugal pumps, in which category mixed- and axial-flow geometries are generally included) would be too low in efficiency to be practical. Rather, rotary positive displacement pumps take over because there is a transition through the drag pump domain. Sometimes called a regenerative or periphery pump, the drag pump is actually a rotodynamic machine, developing head peripherally around the impeller through successive passages radially through the blades on both sides until a barrier is reached at some point on the periphery, where the fluid is then discharged.⁵

The screw pump, on the other hand, is a truly positive displacement (rotary) machine. It can have two, three, or more meshing screws and can move large quantities of fluid—both single- and multiphase—against a large pressure difference Δp , giving it a specific speed range that extends well into centrifugal pump territory. Not shown is the progressive cavity pump, which has a single screw surrounded by an elastomer sealing member.

Lower flow rates are readily accommodated by the vane pump, whereas gear pumps handle a higher range of pressure differences at such flow rates. Finally, extremely high pressures are produced by reciprocating pumps, the specific speed range of which extends off the figure on the left.

Positive displacement pumps appear in Figure 9 in order to provide perspective. The concept of specific speed is not generally applied to these machines, because a given positive displacement pump can have such a wide range of pressure-rise capability at a chosen flow rate and speed as to make it difficult to associate a given rotor geometry with a particular value of specific speed. On the other hand, a unique rotodynamic pump geometry is readily associated with the specific speed of the BEP of such a machine.

Performance of Optimum Geometries Figure 9 enables one to easily identify the pump stage types associated with required pumping tasks in terms of head, flow rate, and rotational speed. Beyond this general picture is the related performance of a real pump geometry in a real fluid. Although, for centrifugal pumps, the specific speed has the major effect on performance, the available *NPSH* and the viscosity of the pumpage also have an influence. These are evident in the following formal statement of the efficiency of an optimized pump (cf Eq. 35)

$$(\eta_{\max})_{\{G_i\}_{\text{opt}}} = f(\Omega_s, \Omega_{ss}, \{2\text{-}\Phi\}, \{\Gamma_p\}, \{\Sigma\}, R_{e,H}, Q) \quad (39)$$

where the radius r_2 , representing the size, has been eliminated from the other variables in Eq. 35 by introducing the *suction specific speed* Ω_{ss} and the *head-flow Reynolds number* $R_{e,H,Q}$, which are defined in Eqs. 40 and 41:

$$R_{e,H,Q} = \frac{\sqrt{Q} (g\Delta H)^{1/4}}{\nu} = R_e \sqrt{Q_s} \psi^{1/4} \quad (40)$$

$$\Omega_{ss} = \frac{\Omega \sqrt{Q}}{(g \text{ NPSH})^{3/4}} = \frac{\sqrt{Q_s}}{(\tau_2/2)^{3/4}} \quad (41)$$

where, the common form of the suction specific speed, called N_{ss} , is given in commercial U.S. units by (Eq. 42)

$$N_{ss, (\text{U.S.})} = \frac{N(\text{rpm}) \sqrt{Q(\text{gpm})}}{[\text{NPSH}(\text{ft})]^{3/4}} = \Omega_{ss} \times 2733.016 \quad (42)$$

Size Effect For sufficiently high *NPSH* (or sufficiently low suction specific speed) and low viscosity (or high Reynolds number), real pumps also possess a strong size effect on efficiency. This is because, in normal manufacturing processes, the clearances δ preventing internal leakage Q_L (for example, past the impeller sealing rings in Figure 2) do not scale up as rapidly as the size (represented by r_2), nor do the surface roughness heights ε . Thus, a larger pump tends to be more efficient. Strictly speaking, however, the geometry of the larger pump is not the same as that of the smaller pump, and this forces one to modify Eq. 39 by reintroducing two of the length ratios G_i that were part of the set $\{G_i\}$ in Eq. 35 which characterize the hydraulic shape of the machine. Thus, Eq. 39, revised to reflect these realities, becomes

$$(\eta_{\max})_{\{G_i\}_{\text{opt}}} = f_1 \left(\Omega_s, \Omega_{ss}, R_{e,H,Q}, \{2\text{-}\Phi\}, \{\Gamma_p\}, \{\Sigma\}, \frac{\varepsilon}{r_2}, \frac{\delta}{r_2} \right) \quad (43)$$

A study of a large number of commercial centrifugal pumps by H. H. Anderson⁶ has quantified Eq. 43 for such machines. These pumps were all operating in water and had sufficient *NPSH* for performance not to be influenced by Ω_{ss} . The results are given by Eq. 44, which is plotted in Figure 10:

$$\eta = 0.94 - 0.08955 \times \left[\frac{Q(\text{gpm})}{N(\text{rpm})} \times X \right]^{-0.21333} - 0.29 \times \left[\log_{10} \left(\frac{2286}{N_s} \right) \right]^2 \quad (44)$$

FIGURE 10 Efficiency of centrifugal pumps versus specific speed, size, and shape—adapted from Anderson⁶. Note: Actual experience for $N_s > 2286$ shows higher efficiency, as indicated by the dashed line.

where
$$X = \left[\frac{140}{\epsilon(\mu - \text{in.})} \right]^2$$

Eq. 44 is a combination of separate relationships described by Anderson for efficiency and speed as functions of flow rate⁶. Included is a correction for specific speed that is too conservative for $N_{s(\text{US})} > 2286$ or Ω_s greater than about unity. With this qualification, Figure 10 is a useful representation for centrifugal pumps and is often as far as many users go in determining the performance of these machines.

Viscosity Effects Centrifugal pump geometries have not generally been optimized versus Reynolds number—often because the effect on hydraulic shape is not very great except for the highest viscosities of the pumpage, and a given application can sometimes experience a substantial range of viscosity. Studies of conventional centrifugal pumps over a range of Reynolds number have been combined in nomographic charts in the Hydraulic Institute Standards, which yield correction factors to the head, efficiency, and flow rate of the BEP of a low-viscosity pump in order to obtain the BEP of that pump when operating at higher viscosity⁷. Figure 11 is a presentation of these correction factors in terms of the head-flow Reynolds number. Strictly speaking, in view of Eq. 43, each pump geometry has a unique set of such correction factors, yet the data presented in Figure 11 have been widely utilized as reasonably representative of conventional centrifugal pumps.

NPSH Effects In many cases, the available *NPSH* is low enough, or the suction-specific speed Ω_{ss} at which the pump stage must operate is high enough for significant two-phase activity to exist within the impeller. This is to be expected in centrifugal impellers of water pumps if the available Ω_{ss} is greater than about 3 to 4 (or $N_{ss(\text{US})} = 8,000$ to 11,000). In such a case, Ω_{ss} and the vaporization quantities $\{2-\Phi\}$ in Eq. 35 dictate a profound change in the impeller geometry into that of an inducer. The inducer has an entering or “eye” diameter that is significantly enlarged—together with tightly wrapped helical blading. Often the inducer is a separate stage that pressurizes the two-phase fluid as needed to provide a sufficiently low value of Ω_{ss} at the entrance of the more typical impeller blading that is immediately downstream of the inducer. If the two-phase fluid is near its thermodynamic critical point, the $\{2-\Phi\}$ operate to greatly reduce the amount of two-phase

Viscous Fluid Effects on Pumps

FIGURE 11 Viscous fluid effects on centrifugal pumps—adapted from Hydraulic Institute ANSI/HI 2000 Edition Pump Standards, Reference 7.

activity within the pump. (At the critical point, the liquid and gas phases are identical, and therefore both have the same specific volume.) An example is the pumping of liquid hydrogen, for which an inducer is unnecessary until much higher values of Ω_{ss} are reached. Moreover, inducers—typically limited to Ω_{ss} -values of about 10 ($N_{ss,US} = 27,000$) in water—can, at sufficiently low tip speed, operate at zero $NPSH$, which corresponds to an infinite value of Ω_{ss} ⁸.

Pumping Entrained Gas In addition to the liquid's own vapor (which is the gas involved in the $NPSH$ -effects discussion), many pumping applications deal with a different gas; that is, a different substance from the liquid being pumped. The effects of this gas on performance arise from a) the volume flow rate of the gas at the inlet, b) the pressure ratio of the pump, which determines how far into the impeller this gas volume persists; that is, how much it gets compressed, and c) how much of the gas dissolves in the liquid as the pressure increases within the pump, which depends on both the solubility and the degree of agitation of the fluid produced by the pump. The set of fluid properties associated with these gas-handling phenomena are represented by (g_p) in Eq. 34, the dimensionless form (Eqs. 35 and 43) of this set being (Γ_p) . Generally, for typical commercial centrifugal pumps, the performance under such conditions usually manifests itself as a loss of pressure rise, which is reasonably stable up to an inlet volume flow rate fraction of gas to liquid of 0.04 to 0.07⁹. Inducers can handle larger inlet volume fractions of gas, and, under Dalton's law for partial pressures, the liquid's own vapor also occupies the volume of the gas bubbles. Single and multistage centrifugal pumps have been built that handle far greater gas volume than these single-stage values^{10,11}; moreover, multiphase rotary positive displacement screw pumps can handle gas volume fractions up to 1 (100 percent gas)¹¹.

Effects of Slurries and Emulsions Finally there is the influence of the dimensionless quantities (Σ) in Eq. 43. Impeller and casing design are altered so as to reduce wear-producing velocities if the pumpage is a slurry of solids contained in a carrier liquid. (Slurry pumps are usually single-stage machines with a collector or volute casing sur-

rounding the impeller.) This usually means a smaller impeller eye diameter (which, as can be seen in Figure 6, reduces the inlet relative velocity W_{1i}) and a larger radial distance from the impeller to the surrounding volute because the circumferential velocity component V_θ of the fluid emerging from the impeller (also seen in Figure 6) slows down with increasing radial position and is then lower in the volute passageway¹². Performance also is altered, depending on the composition and concentration of the slurry. These are complicated non-Newtonian flows and are covered in detail elsewhere in this book in conjunction with a thorough treatment on solids-handling pumps. Emulsions are another example of such flows, many of which are destroyed by excessive local shear in the fluid. For this reason, screw pumps are sometimes utilized for emulsions rather than oversized, slow-running centrifugal pumps. Except for thin layers of the fluid at the clearances, most of the flow in a screw pump experiences very little shear in comparison to the flow through a centrifugal pump.

Electromagnetic Effects Not appearing in Eq. 43 are quantities associated with electromagnetic phenomena. For example, electric current flowing radially outward through fluid contained in an axially directed magnetic field is capable of producing a rotating flow. Called a hydromagnetic pump, this device is therefore “centrifugal,” yet it has no moving parts. Such pumps have been used for liquid metals and could be made reasonably efficient for any pumpage with high conductivity.

DESIGN PROCEDURES

Establishing the Pump Configuration The first step in designing a pump is to determine the type and number of stages that are needed to meet the given set of operating conditions, usually Q , p_1 , p_2 , available $NPSH$ ($= NPSHA$) and specific gravity of the fluid. If the pump must meet several such sets of operating conditions, one set has to be chosen for the BEP or design point so all the others are satisfied, if possible. Making the proper choice of this BEP may require some iteration: first making a trial choice, doing a preliminary design, and determining the corresponding pump performance characteristic curves, and then repeating these steps if necessary.

Pump rotative speed N (rpm) must be chosen in order to proceed. Selection of the highest practical rpm is desirable because it yields the smallest size and therefore usually the lowest cost and easiest containment of system pressure. If, for the chosen number of stages, the stage specific speed is too low, Figure 10 indicates that efficiency is generally improved with greater speed. The maximum possible rpm is that which yields a value for the suction specific speed Ω_{ss} (Eq. 41) or N_{ss} (Eq. 42) that the first stage of the pump can accommodate, where $NPSH$ is found from Eq. 41 as follows:

$$NPSH = \frac{1}{g} \left(\frac{\Omega}{\Omega_{ss}} \right)^{4/3} Q^{2/3} \quad (45)$$

Typically, the Ω_{ss} -capability of an impeller does not exceed a value that is somewhere in the range 3 to 4.5 ($N_{ss} = 8,200$ to 12,300), depending on minimum (off-design) flow rate requirements, and it is typically 10 (27,000) or less for inducers. Generally, the supplier furnishes a pump that has a value of $NPSH$ -capability (or “ $NPSHR$ ”) smaller than the stated $NPSHA$. This difference or “ $NPSH$ -margin” is desirable if there is any uncertainty as to the true value of $NPSHA$. It is essential for high values of Δp_{atg} ; (see discussion of “high-energy pumps” further on in this section.) Often a higher speed can be employed if a double-suction impeller (entry of fluid from both sides) can be used, as then only half of the given Q enters each side of this impeller, and only that half can be used in the Ω_{ss} -equation applying to that fluid and impeller type.

The double-suction configuration is popular for large, single-stage pumps because the axial thrust is nominally zero. It is also found as the first stage in some multistage pumps, in which case the arrangement of the remaining impellers can be “back-to-back” (half of them facing in one direction and half opposite) to achieve axial thrust balance. On the

other hand, the interstage flow passages are simpler if these impellers are all facing in the same direction—in which case the thrust is opposed by a balancing drum or disk as described in Section 2.2.1. Forming the specific speed from N , Q , and ΔH (from Eq. 3) and referring to Figure 9 for the kind of impeller (which then gives one an idea of the other hydraulic components (inlet passage, diffuser and collector, and so on) and Figure 10 for the expected efficiency, one can decide whether the pump would perform better and still meet any installation and size restrictions with more than the one stage implied by this first N_s -calculation.

If the user requires the performance characteristics of a positive displacement pump—such as a wide range of pressure-rise at a nearly constant flow rate Q —selecting such a pump may be possible if the specific speed is not too high. (See Figure 9.) The choice of speed for positive displacement pumps is sometimes determined by mechanical considerations rather than suction capability.

Sizing the Pump The next step is to determine the approximate size of a pump or pump installation. Beginning with the impeller, the agent of the energy transfer to the fluid in a pump, one utilizes the results of the pump hydraulic geometry optimization process. This also yields the proportions of the velocity diagrams that correspond to the geometry associated with the desired value of specific speed. These in turn lead to two major sizing factors for an impeller, which are plotted for typical commercial pumps in Figure 12; namely the head coefficient ψ (originally defined in Eq. 31) and the outlet flow coefficient ϕ_i defined on this figure⁴. Equations in the figure show how these factors are used to determine the exit radius r_2 (or diameter D_2) and the width b_2 (Figure 8) respectively. The flow coefficient ϕ_i is obviously a velocity component ratio. For the head coefficient of a pump with zero inlet prewhirl to the impeller (that is, $V_{\theta,1} = 0$), the relevant

FIGURE 12 Sizing factors for the diameter and width of typical impellers—adapted from Stepanoff⁴.

velocity ratio (see Figure 3) is $V_{\theta,2}/U_2$, which in view of Eqs. 15b and 31 is equal to the ideal head coefficient ψ_i , as this corresponds to the ideal head H_i . Referring to Eq. 15c, it is obvious that the actual head coefficient $\psi = \eta_{HY} \times \psi_i$, or, in the (common) case of zero prewhirl, $\psi_i = V_{\theta,2}/U_2$.

Overall pump dimensions are conveniently viewed in terms of factors times the impeller diameter. The overall diameter exceeds that of the impeller due to the surrounding casing. For single stage pumps, this casing will include a volute and perhaps a set of diffuser vanes immediately surrounding the impeller; so, the casing diameter can be 50% greater than D_2 or more. On multistage pumps (many with radial-outflow diffusers and return vanes), this excess is often less than 50%.

Single-stage pump axial length includes provision for inlet passageways and bearing housings and is therefore approximately the same as the overall pump diameter. On the other hand, the axial length of a stage in a multistage pump is often less than half of the impeller diameter. Minimizing this "stage length" (and diameter) is a goal of competitive pump designers in the quest to create a machine of light weight and low cost. But too small a stage length is accompanied by inferior hydraulic performance because not enough room is provided for the passages around and within the impeller to turn the fluid with minimum loss. Further, the bearing housings and the suction and discharge "heads" or end pieces must be considered in arriving at the overall length of a multistage pump.

This sizing discussion so far has focused on pumps with a radial-outflow geometry. For the axial-flow geometries of higher specific speeds, the situation is simpler. The diameters of the propeller (Figure 9) and any stationary vanes downstream (or upstream) are essentially the same. The approach and discharge piping is of about the same size. A simple guideline for the maximum radius of the propeller is found from the following approximate extrapolation of the ψ -curve of Figure 12:

$$\psi_t = \frac{0.53}{\Omega_s} \quad (46)$$

where the outer radius of the propeller $r_{t,2}$ should be substituted for the mean exit radius r_2 in the ψ -definition. Thus the ψ -curve is in reality a ψ_t -curve for non-radial-flow pumps. For small departures from radial flow, as illustrated in Figure 8, the ψ -curve of Figure 12 can be used either way.

These guidelines are often all that pump users or fluid system designers need to plan their installations. To get beyond this overview, one must pursue the hydraulic design in detail—as afforded by the following development and examples.

Designing the Impeller Determination of the geometrical features of the impeller is generally accomplished in the following order: a) the "eye" radius r_e , b) the exit radius r_2 or $r_{t,2}$, and c) the exit width b_2 or, in the case of mixed- and axial-flow impellers, the hub exit radius $r_{h,2}$ —all of which form the starting point for d) shaping the hub and shroud profiles (Figure 13); and, finally, e) construction of the blades.

a) The eye. The inlet radius of the impeller eye r_e (Figure 13) is nearly the same as $r_{t,1}$, which is the diameter of the tips of the impeller blades at the inlet. This emerges after the eye flow coefficient $\phi_e = V/U_e$ [the ratio of the one-dimensional axial velocity entering the eye (Figure 8) to the tangential speed of the impeller eye $U_e = \Omega r_e$] is known:

$$\phi_e = \frac{Q/A_e}{\Omega r_e} = \frac{\bar{V}_e}{U_e} \quad (47)$$

$$A_e = \pi(r_e^2 - r_s^2) \quad (48)$$

Thus, r_e can be found from the following combination of Eqs. 47 and 48:

FIGURE 13 Hub and shroud profiles of centrifugal pump impeller

$$r_e = \left[\frac{Q}{\pi \Omega \phi_e \left(1 - \frac{r_s^2}{r_e^2} \right)} \right]^{1/3} \quad (49)$$

where the shaft-to-eye ratio r_s/r_e can be estimated at first. Typical values for ϕ_e vary from 0.2 to 0.3 for impellers and down to 0.1 or less for inducers, depending on suction conditions, as can be seen from its relationship to suction-specific speed:

$$\Omega_{ss} = \frac{\Omega \sqrt{Q}}{(g NPSH)^{3/4}} = \sqrt{\pi \phi_e \left(1 - \frac{r_s^2}{r_e^2} \right)} / (\tau/2)^{3/4} \quad (50)$$

where the cavitation coefficient τ (cf. τ_2 in Eq. 36) is defined in terms of the eye speed $U_e = \Omega r_e$ (Table 1). τ is related to ϕ_e through empirical correlations, such as those given in Table 1. (Gongwer's¹³ values for the correlation factors k_1 and k_2 apply to large pumps. The larger "typical" values shown for 3% breakdown apply to the more common smaller sizes. The inducer correlation is a curve fit to the data of Stripling and Acosta¹⁴ for the breakdown value of τ .) Thus one can solve for ϕ_e from a given suction-specific speed and, through Eq. 49, obtain the eye size. However, the value of ϕ_e at the BEP or design point rarely exceeds 0.3, regardless of how much $NPSH$ is available. This ϕ_e -limit therefore applies to impellers that follow and are in series with the first stage in a multistage pump. These are variously referred to as "series" or "intermediate" stages. (Slurry pump impellers are an exception to this guideline, for then the relative velocity is minimized to avoid excessive wear. In this case ϕ_e can be as high as 0.4 and $NPSHA$ is generally more than adequate for these slow-running machines.)

b) The exit radius r_2 (or diameter D_2). This is found from head-coefficient ψ by means of the equation for r_2 in Figure 12. The upper curve for ψ can be used unless detailed performance analysis or a desired non-typical performance characteristic curve indicates otherwise. Eq. 46 can be used for specific speeds Ω_s greater than 1.6 ($N_s > 4373$), where the maximum radius $r_{t,2}$ is computed per the previous discussion accompanying that equation.

c) The exit width b_2 . The equation for exit passage width b_2 in Figure 12 can be used for radial-outflow and mixed-flow impellers, r_2 being located halfway across the passage. This

TABLE 1 *NPSH correlations*

$$\tau \equiv \frac{\text{NPSH}}{U_c^2/2g} \quad \Omega_{ss} = \frac{\sqrt{\pi \phi_c \left(1 - \frac{r_s^2}{r_c^2}\right)}}{(\tau/2)^{3.4}}$$

For breakdown in pressure rise due to two-phase activity in pump

a) Impellers (Gongwer¹³) $\tau = k_1 \frac{V_c^2}{2g} + k_2 \frac{W_{l,sh}^2}{2g}$

$$\text{NPSH}_{3\%} = \left(\frac{k_1}{\frac{V_{l,sh}}{V_c}} \right)^n \frac{V_c^2}{2g} + k_2 \frac{W_{l,sh}^2}{2g}$$

($V_{0,1} = 0$): $\tau_{3\%} \equiv \frac{\text{NPSH}_{3\%}}{U_c^2/2g} = (k_1 + k_2) \phi_c^2 + k_2$

$$\phi_c = \frac{V_c}{U_c} = \frac{Q/A_c}{\Omega r_c}$$

| | Gongwer ¹³ (Large pumps) | Typical (3% breakdown) |
|-------|--|---------------------------|
| k_1 | 1.4 | 1.69 |
| k_2 | 0.085 | 0.102 |

b) Inducers (curve fit to the data of Stripling & Acosta¹⁴)

$$\tau = 0.02 + 0.02 \left[\log_{10} \left(\frac{\phi_c \sin \beta_{l,b,sh}}{1 + \cos \beta_{l,b,sh}} \right) + 3 \right]^{3.5}$$

involves the exit flow coefficient or meridional velocity ratio $\phi_i = V_{m,2}/U_2$, the lower curve of Figure 12 being for typical values of this quantity. The “openness” factor ε allows for blockage due to blade thickness and to the buildup of boundary layers on the surfaces of the passageways (blades and hub and shroud). The value of ε is generally between 0.8 and 0.9, the higher figure applying to larger machines. For axial-flow impellers or propellers and inducers, a choice of the hub-to-tip radius ratio at the exit defines the passage width instead. This ratio decreases with specific speed from about $\frac{2}{3}$ at the right end of Figure 12 to $\frac{1}{3}$ or less at the highest specific speeds.

d) *Hub and shroud profiles.* With the eye and the outlet sizing established, the two are connected by specifying the hub and shroud profiles. Some texts illustrate the variation of hub and shroud profiles with specific speed¹⁵. Although these are excellent guidelines coming from experience, what follows is the approach one would take to synthesize these

shapes on the basis of fundamental fluid dynamical considerations, at the same time taking experience into account. Referring to Figure 13, an acceptable geometry can be achieved by following these guidelines:

- i. Maintaining the meridional flow area $2\pi r_{b,1}b_1$ at the blade leading edge at about the same as it is at the eye, namely $\pi(r_e^2 - r_s^2)$, but then gradually increasing it versus meridional distance to the generally larger value already established at the exit, namely $2\pi r_2b_2$.
- ii. Choosing the minimum radius of curvature R_{sh} of the shroud to be about half the radial opening at the eye. This avoids excessive local velocity $V_{1,sh}$ at the blade leading edge. This has two consequences. Shaping the impeller blades to match a widely varying meridional approach velocity can complicate the construction of these blades. Also, on first-stage impellers, if $V_{1,sh}$ is too great, the local pressure at that location will be closer to the vapor pressure, increasing the required $NPSH$ (or $NPSH_{3\%}$). This is due to a larger resulting value of the empirical factor k_1 , presented in Table 1 as the n^{th} power of the velocity ratio $V_{1,sh}/V_e$. Single-phase theory would require that the exponent $n = 2$, but two-phase activity in the pump reduces the local pressure reduction that a single-phase application of Bernoulli's equation would indicate.

Figure 14 is a plot of the meridional streamlines in the space between the hub and shroud surfaces of the first-stage impeller of a high-energy boiler feed pump in the absence of blades. This was obtained from a computer solution via Katsanis' program¹⁶ of the inviscid axisymmetric flow field, which is governed by the following equation:

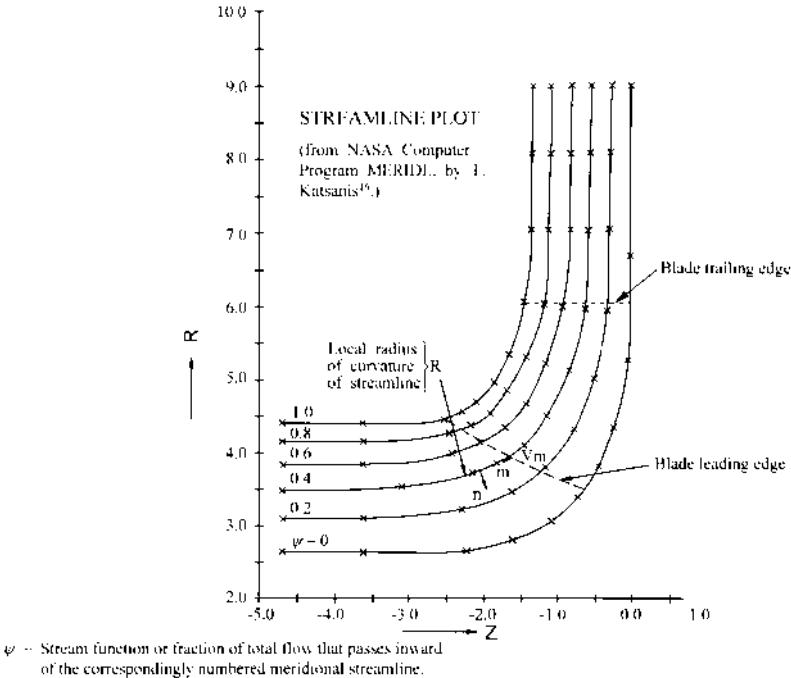

FIGURE 14 Axisymmetric flow analysis for the distribution of meridional velocity V_m along the blade leading edge (Eq. 51a)

$$\frac{dV_m}{dn} = \frac{V_m}{R} \quad (51a)$$

As the average value of V_m at the blade leading edge is about the same as its average V_e in the eye, $V_{1,sh}$ can be estimated from the finite-difference form of this equation, which expresses the change in V_m from shroud to hub in terms of an average radius of curvature R of the meridional streamlines across the passage of width Δn from shroud to hub in the n -direction (normal to the streamlines in Figure 14):

$$\frac{\Delta V_m}{V_m} = \frac{\Delta n}{R} \quad (51b)$$

The estimated average R in Figure 14 is about twice the passage width Δn ; so, by the estimate of Eq. 51b, $\Delta V_m/V_e = \frac{1}{2}$. If half this difference is between V_e and $V_{1,sh}$, then $V_{1,sh}/V_e \approx 1.25$. The computer solution of the inviscid axisymmetric-flow Eq. 51a in this bladeless passage yields $\Delta V_m/V_e = 0.73$ and $V_{1,sh}/V_e = 1.45$ at this location¹⁶. Now, referring to Table 1, raising $V_{1,sh}/V_e$ to the power 1.4 would produce the typical value of 1.69 given for k_1 , which implies that the exponent $n \approx 1.4$. However, two real effects operate to bias $V_{1,sh}/V_e$ toward lesser values; namely, a) greater loss of total pressure of flow entering the impeller along the shroud—due to wall friction and higher velocity, and b) shifting of the flow away from the shroud due to the presence of the impeller blades, which in conventional designs present the incoming flow with the greatest incidence at the hub. This serendipitous state of affairs tends to bring the value of n back toward 2. Moreover, the above estimate of $V_{1,sh}/V_e \approx 1.25$ from Eq. 51b is more typical of the flow for which designers tend to set the impeller blades at the inlet.

These results are strongly influenced by the radius of curvature at the shroud R_{sh} , which in Figure 14 is about half of the passage width Δn . This accords with the guideline for R_{sh} .

- iii. Shaping the hub profile compatibly with the guidelines as stated earlier. This is best done after making an initial estimate of the shroud profile as outlined previously. The distribution of meridional flow area from the eye to the exit should then be specified. From this, a hub profile will emerge. As seen in Figures 13 and 14, the hub of a radial-outflow impeller becomes essentially radial over the outer portion of its extent. If this does not result from this procedure, appropriate adjustments can be made to the shroud profile and the process repeated.
- iv. For a high-specific-speed, axial-flow impeller, or inducer, the hub profile is often a cone or a reverse curve between a smaller radial location at inlet to a larger one at outlet, the latter radius decreasing with increasing specific speed as mentioned earlier. A cone or cylinder for the shroud profile is often found in such machines.

e) Construction of the blades. The blades are designed by i) selecting the locus of the leading and trailing edges in the meridional plane, ii) establishing the surfaces of revolution (streamwise lines in the meridional plane) from inlet to outlet along which the construction proceeds, iii) selecting the inlet angles, iv) selecting the outlet angles, v) establishing the number of blades, and vi) obtaining the blade coordinates from inlet to outlet:

- i. *Leading and trailing edge loci.* If every point along the leading and trailing edges is revolved about the axis of rotation so as to lie in one meridional plane, the loci of these edges appear as shown in Figure 13 or 14. The outer or shroud end of the blade leading edge is positioned at or near the minimum radial location; that is, at or near the eye plane, whereas the inner or hub end is typically well back and largely around the corner along the hub profile. These locations are desirable; first, at the shroud, because the absolute velocity V (typically $= V_m$) approaching the blade begins to decelerate beyond the eye plane, so starting the blade ahead of this decelerating region tends to

prevent separation of the fluid from the shroud surface due to the pumping action in the blade channels¹⁷; and secondly, being far enough along the hub in the streamwise direction to avoid impractical blade shapes (excessive twist, rake, and so on) that would make both the construction and the flow inefficient. The locus of the blade trailing edges is normally straight in the meridional plane and is axial in orientation for most centrifugal pumps. At the higher specific speeds, this locus becomes more and more slanted until it takes on the nearly radial orientation it has for a propeller (Figure 9).

- ii. *Surfaces of revolution for blade construction.* Developing the coordinates of the blades along three streamwise surfaces of revolution—the hub, mean, and shroud, whose intersections with the meridional plane appear as streamwise lines in that plane—usually provides a sufficient framework for shaping the blades of an impeller. However, for high specific-speed impellers, where the passage width in the meridional plane Δn (Figure 14) is large (about equal to or greater than the meridional distance from leading to trailing edge), definition along two intermediate surfaces of revolution is also needed to achieve a satisfactory design.

The “mean” line is one that is representative of the flow from a one-dimensional standpoint as well as for the construction of the blades. Precisely, this is the mass-averaged or “50%” streamline (that is, the streamline for $\psi = 0.5$ in Figure 14)—which evenly divides the mass flow¹⁷. This line is reasonably and conveniently approximated by the “rms streamline,” that is, the line that would result in a uniform meridional velocity distribution from hub to shroud and therefore equal areas $2\pi r \Delta n$ normal to the meridional velocity component V_m . In this case, Δn ($= \Delta b$) is the spacing between the rms streamline and the hub or shroud line. This would put each point on the mean line at the root mean square radial position along a true normal to the meridional streamlines; hence, the “rms” terminology.

- iii. *Inlet blade angles.* The blade angles are set to match the inlet flow field. This is done where each of the previously chosen surfaces of revolution (that intersect the meridional plane in the streamwise lines just described) crosses the chosen locus of the blade leading edges in the meridional plane. At each such crossing point, an inlet velocity diagram of the type shown in Figure 3 is plotted in a plane tangent to the surface of revolution at that point. (Figure 3, representing a purely radial-flow configuration, is a view of such a plane, as the surfaces of revolution are then simply disks.) Each such velocity diagram or triangle contains a specific value of the angle $\beta_{f,1}$ between the relative velocity vector W_1 and the local blade speed vector $U_1 = \Omega r_1$.

The corresponding blade angle $\beta_{b,1}$ between the mean camber line of the blade and the circumferential direction is set equal to $\beta_{f,1}$ or slightly higher than this to allow for the higher $V_{m,1}$ caused by non-zero blade thickness at the leading edge and to allow for higher flow rates that may be called for at off-design conditions. To construct the triangle, one first plots U_1 and then $V_{m,1}$, which is taken from an analysis such as that of Figure 14 (altered as noted previously for the effect of the blades) or is chosen as the mean value $Q/2\pi r_{b,1} b_1$ (Figure 13) at the rms streamline. It is adjusted from experience at the shroud and hub. Likewise, if any prewhirl $V_{\theta,1}$ is delivered to the impeller, it must be taken into account as illustrated in Figure 3.

- iv. *Outlet blade angles.* Whereas the inlet velocity diagrams enable the designer to correctly set the blades to receive the incoming fluid with minimum loss, the outlet velocity diagram displays the evidence—through the magnitude of the circumferential velocity component $V_{\theta,2}$ that the intended head will be delivered by the pump in accordance with Eq. 15c. As shown in Figure 3, $V_{\theta,2}$ is determined—for the given impeller tip speed U_2 —by the exit relative flow angle $\beta_{f,2}$ in conjunction with the exit meridional velocity component $V_{m,2}$. This value of V_m is somewhat larger than that given by Eq. 16 because of a) blockage due to blade thickness and boundary layer displacement thickness and b) the presence of any leakage flow Q_L (Figure 2 and Eq. 11) that may also be flowing through the impeller exit plane or Station 2.

Well inward of the exit plane, the direction of the one-dimensional relative velocity vector W can be assumed to be parallel to the blade surface; however, in the last third

FIGURE 15 Impeller outlet velocity diagram

of the passage, the blade-to-blade distribution of the local relative velocity changes due to the unloading of the blades at the exit. This produces a deviation of the direction of W_2 from that of the blade. This deviation, called “slip” in pumps, results in less energy being delivered to the fluid by the impeller than would be the case if there were “perfect guidance” such as would occur with an infinite number of blades. Accordingly, in the outlet velocity diagram of Figure 15, the relative flow angle β_f is less than the blade angle β_b . This deviation is quantified by the “slip velocity” V_s . The magnitude of V_s depends on the distribution of loading along the blades from inlet to exit and therefore on the geometry of the flow passages and the number of blades. (Without slip, W_2 is the same as the “geometric” relative velocity $W_{g,2}$ shown in the figure.) The slip factor $\mu = V_s/U_2$ —typically between 0.1 and 0.2—was determined theoretically by Busemann for frictionless flow through impellers with logarithmic-spiral blades (constant- β from inlet to exit) and a two-dimensional, radial-flow geometry with parallel hub and shroud¹⁸. Applicability of this theory to typical impellers, despite the differences in geometry and the real fluid effects, was found to be good by Wiesner, who represented Busemann’s results by the following convenient approximation¹⁹:

$$\mu \equiv \frac{V_s}{U_2} = \frac{\sqrt{\sin \beta_2}}{n_b^{0.7}} \quad (52)$$

A broader, empirical slip correlation for pumps was developed by Pfeleiderer, taking into account impeller geometry and blade loading, as well as the influence of the downstream collecting system (volute or diffuser)²⁰. Pfeleiderer computes the slip velocity as the product of a slip factor p and the impeller exit tangential velocity $V_{\theta,2}$, where p is computed as shown in Table 2. This table also contains a simple example; namely, a radial flow impeller of a volute pump, for which the resulting value of μ is 0.1826—versus 0.1498 via Eq. 52; however, in this case the latter result is low by about 15 percent. A study of the Busemann plots in Wiesner’s paper yields $\mu = 0.18$. Yet, if this had been a vaned-diffuser pump, Pfeleiderer would have predicted $\mu = 0.1468$ for the same impeller, as it would have delivered more $V_{\theta,2}$ for the same $\beta_{b,2}$, $W_{g,2}$, and, therefore, $V_{\theta,2}$, (Figure 15). This stems from the factor “a” in Table 2 having the value 0.6 (for a vaned diffuser) instead of 0.8 (for a volute). So by this combination of circumstances—and in this example—Eq. 52 describes the slip of a diffuser pump impeller. But, despite the simplicity of Eq. 52, Pfeleiderer’s method (Table 2) would appear to be a more rational, comprehensive, and satisfying method for estimating slip in real pumps.

So, to find the outlet blade angle, the designer begins by deciding upon the required value of $V_{\theta,2}$; finds the exit flow angle and other elements of the diagram assuming the existence of slip. Next, the designer computes the slip and then obtains the value of the outlet blade angle $\beta_{b,2}$. The process is iterative because the forementioned blockage depends on the blade angle as well as the thickness.

TABLE 2 Pfleiderer's slip formulaSlip Velocity V_s :

$$V_s = p V_{\theta,2}$$

$$\left[\Rightarrow \frac{V_{\theta,z,2}}{V_{\theta,2}} = 1 + p \right]$$

where

$$p = \frac{\psi' r_2^2}{z \int_1^2 r \, dm}$$

and where $\psi' = a \times (1 + \sin \beta_2)$
 (or $\beta_{b,2}$)

and $a = \begin{cases} 0.6 \text{ Diffuser (vaned)} \\ 0.65 - 0.85 \text{ Volute} \\ 0.85 - 1.0 \text{ Vaneless diffuser} \end{cases}$

$$\left\{ \begin{aligned} \Rightarrow \int_1^2 r \, dm &= \frac{1}{2} (r_2^2 - r_1^2) \\ &= \left(\frac{r_2^2 - r_1^2}{2} \right) \times (r_2 - r_1) \end{aligned} \right.$$

$$\left\{ \begin{aligned} \text{Example: } r_2 &= 1 ; r_1 = 0.4 ; V_{\theta,2} = \frac{U_2}{2} ; \\ z &= 7 ; \beta_2 = 20^\circ ; \\ a &= 0.8 \text{ (volute)} \\ \psi' &= 0.8 \times (1 + 0.342) \end{aligned} \right. \left\{ \begin{aligned} p &= \frac{V_s}{V_{\theta,2}} = \frac{0.8 \times (1 + 0.342) \times 1^2}{7 \times \frac{1 + 0.4}{2} \times 0.6} = 0.3652 \\ \mu &= \frac{V_s}{U_2} = p \times \frac{V_{\theta,2}}{U_2} = 0.3652 \times \frac{1}{2} = 0.1826 \end{aligned} \right.$$

- v. *Number of blades.* The choice of the number of impeller blades is influenced by a) interaction of the flow and pressure fields of the impeller and adjacent vaned structures such as the volute tongues or diffuser vanes and b) the need to maintain smooth, attached—and therefore efficient—fluid flow within the impeller passages. The effect of the number of blades on the interaction phenomenon is addressed in the latter part of this section under the topic of high-energy pumps, where this issue becomes critical. Smooth, attached flow is assured if the product of the number of blades and their total arc length ℓ along a given meridional streamline, as illustrated in Figure 16, is of sufficient magnitude. Divided by a representative circumference on that streamline, usually that of the impeller outer diameter (OD), this product is called the solidity σ :

$$\sigma = \frac{n_b \times \ell}{2\pi r_2} \quad (53)$$

In practice, solidity varies from about 1.8 at low specific speed ($\Omega_s < 0.4$ or $N_s < 1093$) to slightly less than unity at $\Omega_s = 3$ ($N_s = 8199$). For example, Diczas' curve²¹ is

$V_{m,o}$ is the local meridional velocity component neglecting blockage. (One-dimensionally, $V_{m,o}$ is the value of V_m found from Eq. 16, where the radius r is that from the axis of rotation to the center of the circle of diameter b in Figure 8, which in turn lies on an imaginary line in Figure 8 that is normal to the hub, shroud, and intermediate stream surfaces.) Here, ΔW_b emerges by applying Bernoulli's equation [Eq. 21 with no change in radius (that is, no change in U) or loss as one traverses from pressure side to suction side of the passage] to the static pressure difference $p_p - p_s$ arising from the delivery of angular momentum to the fluid (Eq. 26). This in turn results from the application of the shaft torque to the blades. It is also assumed in the derivation of Eq. 54 that the *blade-to-blade average relative velocity W lies halfway between the surface velocities W_s and W_p* , (which would exist just outside the boundary layers on the blades,) as illustrated in Figure 17. This is a good assumption for efficient flow well within a bladed channel²². ΔW_b is inversely proportional to the solidity because, on the average, from inlet to outlet, Eq. 54 becomes

$$\overline{W_s - W_p} = \overline{\Delta W_b} \approx \left(\frac{2\pi r_2 \sin \beta}{n_b \Delta m} \right) \Delta \left(\frac{r}{r_2} V_\theta \right) \quad (55)$$

where it can be seen from Figure 16 and Eq. 53 that the fraction involving the number of blades n_b is the reciprocal of the solidity σ because

$$\ell = \Delta m / \sin \beta \quad (56)$$

For unconventional impeller geometries, the foregoing solidity guidelines may be inadequate to assure efficient flow. For any geometry, though, the concept of a diffusion factor D , utilized by NACA researchers²³ to assess stationary cascades of airfoils can be employed. In view of Eqs. 53–56, their equation for D takes the following form for both axial- and non-axial-flow geometries, rotating or not:

$$D = 1 - \frac{W_2}{W_1} + \frac{\Delta \left(\frac{r}{r_2} V_\theta \right)}{2\sigma W_1} \quad (57)$$

This can be deduced from Figure 17 as follows:

$$D = \frac{W_1 - W_2}{W_1} + \frac{\overline{\Delta W_b}}{2W_1} \left(\approx \frac{\Delta W_{\text{diffusion}}}{W_1} \right) \quad (58)$$

Then, Eq. 57 is obtained through the definitions of the average value of ΔW_b (Eq. 55 with Eq. 56) and σ (Eq. 53). NACA researchers found that losses increase rapidly if $D > 0.6$. However, many centrifugal pump impellers have virtually the same value of relative velocity W at in and at outlet—along the rms streamline (Figure 17), so D from Eq. 57 is less than 0.6 on the rms streamline and even negative along the hub streamline. This situation was encountered in accelerating (turbine) cascades and led to the use of local diffusion factors, one for each side of the blade, namely D_p and D_s . Here, inspection of Figure 17 and Eq. 58 leads to

$$D_p = 1 - \frac{W_{p, \min}}{W_1} \quad ; \quad D_s = 1 - \frac{W_2}{W_{s, \max}} \quad (59a \text{ and } b)$$

where the 0.6 limit applies individually to D_p and D_s —or to the sum of the two, in which case the limit is 1.2. Eqs. 59a and 59b, therefore, constitute a more useful form

of the diffusion factor concept for assessing the blade loading and the choice of the number of blades in centrifugal pump impellers²⁴.

Finally, the total blade length or number of blades, should not exceed that necessary to limit the diffusion as just described, as this adds unnecessary skin friction drag, which causes a reduction in efficiency. Thus the solidity values given in conjunction with Eq. 53 should not be appreciably exceeded, unless blade load needs to be reduced to lower levels, as with inducers to limit cavitation⁸ or impellers for pumps that must produce lower levels of pressure pulsations.

- vi. *Development of the blade shape.* Blades are developed by defining the intersection of the mean blade surface (really an imaginary surface) or camber line on one or more nested surfaces of revolution. Two such surfaces are formed by the hub and shroud profiles. If the blade shape is two-dimensional (that is, the same shape at all axial positions z), the mean blade surface is completely defined by constructing it on only one such surface of revolution. Generally, however, the shape is three-dimensional and is a fit to the shapes constructed on two or more of these surfaces of revolution; namely, the hub and shroud and usually at least one surface between them. After this final shape is known, half of the blade thickness is added to each side. (Sometimes the full blade thickness is added to one side only, meaning that the constructed surface just mentioned ends up—usually—as the pressure side of the finished blade rather than the mean or “camber” surface. The effective blade angles are then slightly different from those of the pressure side used in the construction process.) The construction along a mean surface of revolution is illustrated in Figure 18. The distribution of the local blade angle β (or more precisely, β_b) is found first by either the “point-by-point” method or the *conformal transformation* method—both of which yield the polar coordinates of the blade, r , θ , and z . These coordinates also depend on the chosen shapes of the intersections of the surfaces of revolution with the meridional plane; that is, the hub, shroud, and mean meridional “streamline” or rms line, as in Figure 18c, and the fact that, on the surface of revolution Figure 18a, $\tan \beta = \text{arc } bc / \text{arc } ac = dm / dy$. The elemental tangential length dy ($= \text{arc } ac$) is the same on both the surface of revolution (Figure 18a) and in the polar view (Figure 18b). From Figure 18b, it is seen that $dy = r d\theta$, so the “wrap” angle θ is found from

FIGURE 18 Blade construction: a) view of construction surface of revolution; b) polar view; c) meridional view

$$\tan \beta_b = \frac{dm}{rd\theta} \quad (60)$$

and r and z are found from the fact that the coordinate m along each of the construction surfaces is a function of r and z (Figure 18c).

If the blade is two-dimensional, its mean surface consists of a series of straight-line axial elements, each having a unique r and θ at all z . Such a blade is typical of low-specific-speed, radial-flow impellers, and can be easily constructed by the “point-by-point” method. Here, one specifies the distribution of W_g —often linear as in Figure 17—after determining the hub and shroud profiles and the corresponding distribution of V_m ¹⁵. In effect, one obtains the distribution of the blade angle β_b by constructing a velocity diagram like the one in Figure 15 at every m -location from inlet (1) to outlet (2) in Figure 18c, dealing only with the “geometric” or non-deviated velocities, in order to get a smooth variation of the blade angle β_b vs m . Allowance is made for blockage due to the thickness of the blades and the displacement thickness of the boundary layers in the passage. The resulting wrap angle θ for each m -point—as well as the corresponding r and z —is then found from Eq. 60. (For convenience in designing the blades, the construction angle θ is often taken as positive as one advances from impeller inlet to exit. For most impellers, this turns out to be opposite to the direction of rotation; and θ is taken in the direction of rotation for most other purposes of pump design and analysis.) As discussed previously in Paragraph iv and illustrated in Figure 17, the actual flow will deviate from the resulting blade via the “slip” phenomenon.

The point-by-point method allows the designer to exercise control over the relative velocity distributions on the blade surfaces (Eq. 54 and Figure 17) via specification of the distribution of W_g or other velocity component in Figure 15; for example, V_a . This becomes more important if an unconventional impeller geometry is being developed¹⁷.

The point-by-point method can also be used for three-dimensional blades. A simple approach in this respect would be to use this method to determine the blade shape along the rms- or 50%-streamline (that is, on the mean surface of revolution depicted in Figure 18). The shapes on the other streamlines, generally the hub and the shroud, can also be found by this method. The resulting overall blade shape, however, is subject to the condition that the resulting wrap $\theta_2 - \theta_1$ cannot greatly differ on all streamlines without the blade taking on a shape that is difficult to manufacture and which may turn out to be structurally unsound or create additional flow losses. This is because the final blade shape is the result of stacking the shapes that have been established on the nested stream surfaces defined by these meridional streamlines. Blade forces due to twists arising from this stacking could modify the expected flow and cause unexpected diffusion losses.

One way to generate blade shapes along the hub and shroud that have the same (or nearly the same) wrap as that obtained from point-by-point construction of the blade on the mean surface of revolution is to establish the desired inlet and outlet blade angles β_b on each such surface and then mathematically fit a smooth shape $y(m)$ to these end and wrap conditions, where y is the tangential coordinate seen in Figure 18 and defined in Figure 19. A conformal representation of the shapes of the blades resulting from such a procedure on each of the three surfaces is seen in Figure 19. These shapes are sometimes called “grid-lines” or simply “grids”—from the description of the graphical procedure that relates these shapes in the conformal representation to those on the actual, physical surfaces⁴. In such a representation, the blade angles are the same as they are on the physical surface of revolution because $\tan \beta = dm/dy$ and $dy = rd\theta$, also yielding Eq. 60.

If the associated distributions of W_g and V_m are smooth, one can expect to have a satisfactory result if these conformal representations are also smooth. Thus, many skilled designers bypass the computations just described for the point-by-point method and use the *conformal transformation* method of blade design. Here, one simply establishes the grid-line shapes by eye in the conformal plane of Figure 19, specifying the blade angles β at inlet and outlet by the previous procedures as the starting point for

FIGURE 19 Conformal transformation of blade shape: "grid-lines"

drawing each grid-line. This conformal blade shape is then transformed onto the physical surface, the differential tangential distance dy becoming $r d\theta$ on the physical surface (Figure 18) and the differential meridional distance dm being identical in both the conformal and physical representations. If the resulting blade shape appears to be unsatisfactory, the designer repeats this process, possibly first altering the hub and shroud profiles or the blade leading and trailing edge locations on these profiles and recomputing the β 's.

Designing the Collector The fluid emerging from the impeller is conducted to the pump discharge port or entry to another stage by the collecting configuration, which can employ one or more of the following elements in combination: a) *volute*s, which can be used for designs of all specific speeds, b) *diffuser* or *stator vanes*, which are often more economical of space in high-specific-speed single-stage pumps and in multistage pumps, and for the latter, c) *return* or *crossover passages*, which bring the fluid from the volute or diffuser to the eye of the next-stage impeller. Generally, the most efficient impeller has a steady internal relative flow field as it rotates in proximity to these configurations. This is assured by all of these elements because they are designed to maintain uniform static pressure around the impeller periphery—at least at the design point or BEP. An exception to this rule is the concentric, "doughnut"-type, "circular-volute" collector, which is used on small pumps or in special instances where the uniform pressure condition is desired at zero flow rate.

The proximity of stationary vanes in these collecting configurations to the impeller must be considered in their design. Called "Gap B," the meridional clearance between the exit of the impeller blades and adjacent vanes ranges from 4 to 15 percent of the impeller radius, volutes having higher values in this range than diffusers, and pumps of higher energy level requiring the larger values. If these gaps are too small, the interactions of the pressure fields of the adjacent blade and vane rows passing each other can cause vibration and structural failure of impeller blades, diffuser vanes, and volute tongues.

a) *Volute*s. A volute is built by distributing its cross-sectional area on a "base circle" that touches the tongue or "cutwater" and is meridionally removed from the impeller exit by

everywhere in the volute²⁵. One-dimensionally, this means that $r_T V_{\theta T} = r_2 V_{\theta 2}$; and, if the velocity V_T is essentially tangential (in the θ -direction), $r_T V_T \cong r_2 V_{\theta 2}$. The diffusion or reduction of the velocity V from the impeller periphery at r_2 to the larger r_T of the throat produces a static pressure increase above that at the impeller exit; however, friction losses in the volute would cause a reduction in static pressure around the impeller at r_2 from tongue to throat unless the throat area $A_T = Q/V_T$ is slightly enlarged, creating a little more diffusion to compensate for this loss. Thus, in practice, at the BEP,

$$r_T V_T \cong (0.9 \text{ to } 0.95) \times r_2 V_{\theta 2} \quad (61)$$

At off-BEP conditions, the volute will be either too large or too small and Eq. 61 will not be satisfied. When the flow coefficient (or Q/N) drops below the BEP value, there will be excessive diffusion and an increase of static pressure around the volute from the zero area point around to the maximum area point at the throat. Proceeding around further, past the throat, a sudden drop in pressure occurs across the tongue to bring the pressure back to what it was at the starting point²⁵. The opposite situation occurs above BEP.

Each of these off-BEP circumferential static pressure distributions is properly viewed as the consequence of a mismatch between the head-versus-flow characteristics of the impeller and volute²⁶. For the impeller, there is the falling, straight, H_i -versus- Q line or “impeller line” of Figure 6, whereas the volute characteristic or “casing line” would be a straight line starting at the origin of Figure 6 and crossing the impeller line at the match point, which is generally at or close to the BEP flow rate. This casing line is straight because the throat velocity V_T varies directly with flow rate Q and, through Eq. 61, directly with the ideal head H_i —because $\Omega \times r_2 V_{\theta 2} = H_i$ (Eq. 15b for $V_{\theta 1} = 0$). In other words, the same volute could be optimum at a different value of Q if it were paired with another impeller whose H_i -versus- Q line crossed this same casing line at that different Q .

To essentially eliminate the consequent radial thrust on the impellers of large pumps at off-BEP conditions, a double volute is used; that is, there are two throats, 180 degrees apart, there being either two discharge ports or a connecting “back channel” to carry the fluid from one of the throats around to join the flow emerging from the other—to form a single discharge port.

The value of the volute cross-sectional area A_v at a given polar position θ_v can be found for the portion of the total pump flow rate Q being carried in the volute at that θ_v -position together with the condition $rV_\theta = \text{constant}$ versus radius. This will produce a distribution $A_v(\theta)$ that is slightly below a straight-line variation versus θ_v from zero to A_T . Often, the practice is to use the latter straight-line design because this produces larger values of A_v where the hydraulic radius of the volute is small, thus compensating for the greater friction loss in that region through lower velocity—particularly for the smaller pump sizes. The cross-sectional shape of the volute is dictated by the need to make a minimum-loss transition from a small area at the beginning of the volute where the height (as can be deduced from Figure 20b) is much smaller than the width b_3 to the throat, for which the height (to the outer casing wall at r_w) and the width b_{\max} are more nearly equal. Too small an aspect ratio (height/width) decreases the hydraulic diameter too much and increases the loss. There is another transition from the throat through an essentially conical diffuser (which may negotiate a turn) to a larger, circular exit port. This diffuser can be designed with the help of charts of flow elements and will normally have a 7-deg. angle of divergence and a discharge area up to twice that of the throat A_T ²⁷. Thus, there is a substantial diffusion from the impeller periphery to the pump or stage exit port. This generally produces a static pressure rise in the collection system that is 20 to 25 percent of that of the whole stage.

b) Vaned diffusers. A vaned diffuser is rotationally symmetric and, if properly applied, produces minimal radial thrust over the whole flow rate range of a pump. Although diffusion can be accomplished in a radial outflow configuration without vanes due to the essential constancy of the angular momentum per unit mass rV_θ , one rarely finds a pump with a vaneless diffuser, partly because so much radial distance is needed to effect the reduction of tangential velocity required, as well as the still larger volute needed on single-stage

FIGURE 21 Vaned diffuser

pumps to collect the fluid at the exit of such a diffuser. Also, the absolute flow angle α_2 (Figure 15) of the fluid leaving the impeller is usually too small to satisfy the conditions for stall-free flow in a vaneless diffuser²⁸. A vaned diffuser, on the other hand, can accomplish the reduction of velocity in a shorter radial distance. Also it can diffuse axially and, to a degree, even with radially inward flow.

Vaned diffusers are similar to multiple volutes in concept, except they are subject to off-design flow instabilities if not shaped correctly. Width b_3 is usually slightly greater than b_2 in order to accommodate discrepancies in the axial positions of impellers that feed them. With reference to Figure 21, "Gap B" ($= r_3 - r_2$) is in effect a short vaneless diffuser, and by the time the fluid has reached the throat (the dashed line at Station 4), it has gained a substantial portion of the static pressure recovery that takes place via diffusion from Station 2 to Station "ex." This "pre-diffusion" is enhanced by the fact that the throat area at Station 4 ($= b_3 w_1$ per passage for parallel-walled radial-flow diffusers) is larger than it is for volutes, the following relation applying to diffusers²⁹:

$$r_T V_T \cong 0.8 r_2 V_{\theta, 2} \quad (62)$$

Therefore, more diffusion than would result from applying Eq. 61 occurs in a vaned diffuser; the skin friction loss due to an otherwise higher velocity at the throat being offset by an efficient reduction of the velocity up to that point and a lower velocity onward.

The fully vaned portion from throat to exit (Figure 21), which performs most of the rest of the diffusion and associated static pressure recovery of the stage, is designed to perform efficiently and maintain stable flow. For typical radial-flow geometries with parallel walls, the vanes can be of constant thickness and comparatively thin or can thicken up to form "islands." The latter approach usually produces a channel that is two-dimensional with straight sides diverging at an included angle, length-to-entrance width ℓ/w_1 , and area ratio A_{ex}/A_T in a combination that avoids appreciable stall³⁰. A typical combination is an included angle of $11\frac{1}{2}$ deg, $\ell/w_1 = 4$, and $A_{ex}/A_T = 1.8$, which also applies for vanes of constant thickness, as illustrated in Figure 21. Constant thickness vanes have curvature. This modifies the performance somewhat^{31,32}, but it allows a smaller overall radius ratio of the diffuser, r_{ex}/r_3 .

Also, this ratio r_{ex}/r_3 will be smaller as the number of vanes n_v increases. The best experience seems to be with diffusers that have only a few more vanes than the number of impeller blades n_b (n_b rarely exceeds 7 in traditional commercial pumps). For pumps of higher energy levels (or high head per stage, as discussed further on in connection with high-energy pumps), it is important that n_v be chosen so as to avoid a difference of 0 or 1 between n_b and n_v or their multiples—up to at least the third multiple or "order" of each. A difference of 2 should also be avoided for at least the lower orders³³.

At off-design flow-coefficients (or off-design flow rate at a constant speed), the angle α of the absolute velocity vector V (Figure 15) approaching the diffuser will vary; yet, for typ-

ical stages, a wide range of flow coefficient is possible without damaging instabilities, even at high energy levels. This is likely the case because α is rather small at the design point or BEP (except for designs having high specific speed), so variations of the angle that occur with flow changes are within the unstalled performance range of the diffuser vane system.

c) Return passages. Conducting the relatively low-velocity fluid from the diffuser to the eye of the next impeller in a multistage pump is accomplished with return vanes or passages that also deswirl the fluid wholly or partially. Except for development of stall in the diffuser, these passages will not see a changing angle of the approaching velocity vector because the diffuser feeding them is a stationary element. In radial-flow pumps, there is a sharp turn in the meridional plane in order to redirect the fluid inward. The fluid, still possessing a circumferential component of velocity that is greater than the meridional component, actually sees a much gentler turn. However, downstream of this point, a sharp turn of the blades is invariably a feature of a return passage; and this, together with the need to ensure undistorted flow into the following impeller, often dictates that the vane system accelerate the fluid as it approaches the eye. Although losses in the return passages—being related to the low velocity within them—have a minor effect on the overall stage efficiency, the design of such passages must ensure unstalled flow into the impeller in order to avoid the negative impact of a distorted inlet flow on the efficiency and to promote pulsation-free operation of the impeller.

A variety of return-passage geometries exist, some of which are presented in the literature^{29,34}. The continuous-vane type is integral with the upstream diffuser, thereby eliminating the entry losses into yet another vane system after the diffuser^{4,34}. Improvements in manufacturing technology have made this potentially more efficient approach more viable for radial machinery. The continuous-vane concept is standard practice in the design of mixed-flow “bowl”-type pumps²¹. The diffusing stator vane row that receives the fluid from the impeller of an axial-flow pump—being an axial-flow element itself—possesses the return feature already. Diffusion in axial-flow stators is typically accomplished by a reduction in velocity of about 30 to 40 percent. The actual value is governed by an acceptable level of the diffusion factor, Eq. 57. (A similar reduction in relative velocity is needed for an axial-flow impeller to generate static pressure, as can be seen from Eq. 21. By comparison, centrifugal impellers, on the rms streamline, usually have W_2 about equal to W_1 —as seen in Figure 17.)

Axial-Flow Pumps The preceding development, though general, is applicable mainly to centrifugal and mixed-flow pumps. In that procedure, the impellers have appreciable solidity, and original blade shapes are constructed from the viewpoint of one- or two-dimensional channel flow. The collectors are often volutes or non-axial-flow vane systems. Performance is not known *a priori* and so must be estimated, as outlined further on. On the other hand, the extensive two-dimensional, experimental, axial-flow cascade data amassed by NACA researchers²³ and others enables the designer to adopt existing airfoil blade shapes and so predict the performance with greater confidence. The procedure for utilizing these shapes and the corresponding experimental results has long been the basis for designing axial-flow compressors for gas-turbine engines and is clearly described by Hill and Peterson³⁵. This approach is widely used, especially for high-specific-speed, low-solidity axial-flow propeller pumps—in designing both rotating and stationary blade rows. Insights for propeller pump design and performance characteristics can be found in Stepanoff³.

An exception to this axial-flow pump design approach is the case of inducers. Although they are axial flow pumps, they have high solidity and are usually designed as channel-flow machines. The design philosophy outlined in the preceding paragraphs is applicable, except that the blades usually approximate constant- or variable-pitch helices. Performance prediction is generally accomplished via one-dimensional calculations and the correlations described in the following paragraphs.

PREDICTING THE PERFORMANCE CURVES

The choices made in the foregoing design procedures can and should be verified analytically, the objectives being first to generate the performance characteristic curves for head

and power at constant speed and second to ensure stable behavior of the various systems in which the pump is to be applied. For the first objective, the solution involves analytical or empirical approaches: a) at non-recirculating flow conditions; that is, from flow rates Q somewhat below Q_{BEP} out to the maximum “runout” flow rate, b) at shut-off ($Q = 0$) and low flow, or c) the complete set of curves for a given pump predicted by means of computational fluid dynamics (CFD).

Generating Performance Curves The fluid dynamical limitation on the deceleration of the relative velocity W determines the shape of the head-versus-flow curves. This is inherent in the choice made for the head coefficient ψ in Figure 12, which sizes the impeller and is illustrated in Figure 22. The typical situation of zero (or nearly so) inlet whirl $V_{\theta,1} = 0$ means that the ideal head coefficient ψ_i equals the most significant ratio of the outlet velocity diagram because from Eqs. 15 and 31 (with for $V_{\theta,1} = 0$):

$$\psi_{\text{ideal}} = \frac{\mathcal{U}_2^2 (V_{\theta,2}/U_2)}{\mathcal{U}_2^2} \quad (63)$$

$$\psi = \eta_{HY} \psi_{\text{ideal}} = \eta_{HY} \frac{V_{\theta,2}}{U_2} \quad (64)$$

Figure 22 illustrates how specific speed Ω_s affects the BEP value of ψ_i and therefore ψ . Overall, only a small reduction of W occurs in most impellers. So, at low Ω_s , the low value of W_i associated with the small eye relative to the maximum diameter (Figure 9) enables the outlet velocity diagram (Figure 22a) to have a high value of $V_{\theta,2}/U_2$. On the other hand, this ratio drops as Ω_s increases and the eye grows to be as large as the maximum diameter of the wheel. Figure 22b is the result because the value of ψ at shut-off (about $\frac{1}{2}$) is not based on the one-dimensional concept of velocity diagrams but primarily on the pressure generated by solid body rotation of stalled (though recirculating) fluid contained within the impeller. The BEP values of ψ in Figure 22b are consistent with Figure 12 and illustrate why a high-specific-speed impeller has such a substantial “rise to shut-off” of the head curve. This is dramatically illustrated in Figures 8–10 of Section 2.3.1 in which the head curves are normalized to that of the BEP³⁶.

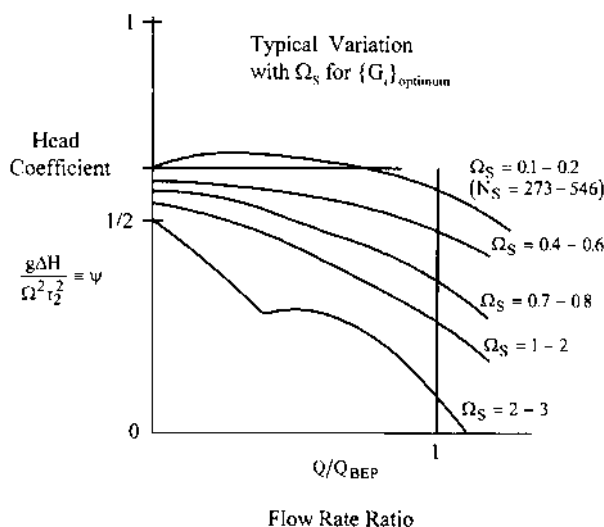

a) Non-recirculating flows. The BEP efficiency and head can be determined from correlations for typical pumps or from computation of the losses. Fluid dynamic procedures described in this section can be used to determine the shapes of the head and power curves at all flow rates to runout, using the BEP as an anchor point for such computations. For pumps designed conventionally, beginning with Figure 12, Anderson’s overall (BEP) efficiency correlation (Eq. 44) as modified in Figure 10 is useful. Other similar charts, especially Figure 6 in Section 2.3.1, are in widespread use. The breakdown of the losses involved, as expressed by Eqs. 8–11, is quantified through the development of the three component efficiencies η_{HY} , η_m , and η_o in Table 3. All three decrease with decreasing specific speed—as might be expected from the charts just mentioned.

This can be seen in the η_{HY} -expression (a) of Table 3 because ψ_i is greater at low Ω_s as discussed relative to Figure 22. Jekat’s η_{HY} -expression (b) of the table works surprisingly well, largely because of the flow effect in Figure 9 (explained there as the “size effect” of larger relative roughness and clearances in smaller pumps) and because low Ω_s tends to go hand-in-hand with low flow rate Q .

To compute η_{HY} at $Q \neq Q_{\text{BEP}}$ (and, if required, at $Q = Q_{\text{BEP}}$ as well), it is necessary to go deeper into the prediction of η_{HY} by developing *expressions for the losses* noted in Eq. 21, which are basically expansions of the expression for the collector loss coefficient ζ_c ²⁶ and for the impeller loss expression (c) of Table 3³⁷. In this expression, the incidence loss coefficient k can be obtained from cascade data or developed as a combination of a turning and a sudden expansion loss^{4,8,27}. The “pipe-type friction factor” f can be increased to include secondary flow and diffusion losses due to blade loading (or turning³⁸ of the absolute velocity vector V). The resulting f -value can thus be twice the usual pipe value associated with the skin friction losses in the passage. (The pipe value of f is found from the well-known

a) velocity diagrams at BEP

b) head-vs-flow curves

FIGURE 22 Performance versus specific speed: a) velocity diagrams at BEP; b) head-versus flow curves.

pipe friction chart—Figure 31 in Section 8.1—by substituting a representative average passage hydraulic diameter $D_h = 4A_p/\wp$ for the pipe diameter d .) A further increase in this f -value occurs if the impeller is missing one or both rotating shrouds; that is, it is a semi- or fully-open impeller with blade tip leakage losses appearing in the main flow stream³⁹. Multiphase flows in pumps often are accompanied by greater than normal hydraulic losses; for example, increasing the concentration of solids in the carrier liquid flowing through a slurry pump increases the f -value still further⁴⁰ (see Section 9.16.2).

*Quasi three-dimensional (Q3D) analysis*⁴¹ affords an assessment of the secondary flow and diffusion losses and gives results similar to inviscid three-dimensional (3D) flow analysis. Q3D analysis starts by solving the 2D meridional (hub-to-shroud) flow field—as in Figure 14, but with blades present. This is followed by a series of 2D blade-to-blade

TABLE 3 Component efficiency expressions developed

A) Hydraulic Efficiency

Breaking up the main flow losses into impeller (including inlet)

and collector losses $\sum_i L_i = L_{\text{imp}} + L_c$ and defining $L_c = \zeta_c \frac{V_2^2}{2}$, where ζ_c

is the collector loss coefficient or fraction of $V_2^2/2$ not converted into static pressure rise in the collector, we have (Eq. 10)

$$\eta_{HY} = 1 - \frac{\sum L_i}{\Delta(UV_\theta)} = 1 - \underbrace{\frac{L_{\text{imp}}}{\Delta(UV_\theta)}}_{\eta_I} - \underbrace{\frac{\zeta_c V_2^2/2}{\Delta(UV_\theta)}}_{\zeta_c \left(\frac{\psi_{i,2}}{2} + \frac{\phi_{i,2}^2}{2\psi_{i,2}} \right)}$$

or, for no inlet whirl ($V_{\theta,1}=0$) $\psi_i = \psi_{i,2}$: 1231

$$\eta_{HY} = \eta_I - \zeta_c \left(\frac{\psi_i}{2} + \frac{\phi_{i,2}^2}{2\psi_i} \right) \quad (a)$$

Impeller hydraulic efficiency: $(\eta_I \approx 0.90 - 0.95)$

Collector loss: $(\psi_i/2 \text{ predominates})$
 $(\zeta_c \approx 0.2 - 0.3)$

Practical experience (roughness ϵ constant for all sizes) yields the formula by W.K. Jekat:

$$\eta_{HY} \approx 1 - 0.8/[Q(\text{gpm})]^{0.25} \quad (b)$$

$$\text{or} \quad \eta_{HY} \approx 1 - 0.071/[Q(\text{m}^3/\text{s})]^{0.25}$$

at all specific speeds.

However a deeper analysis treats losses L_{imp} as follows:

$$L_{\text{imp}} = k \frac{W_1^2}{2} + f \frac{\overline{W^2}}{2} \frac{\ell}{D_h} \quad (c)$$

where D_h = passage hydraulic diameter,

ℓ = passage length

f = pipe-type friction factor

k = incidence loss coefficient

$\overline{W^2}$ = the average square of the relative velocity within the passage along the rms or mean meridional streamline

W_1 = relative velocity just upstream of the impeller blades on the rms streamline

TABLE 3 Continued.

B) Mechanical Efficiency

From Eq. 9,

$$\eta_m = \frac{P_s - (P_{DF} + P_{B\&S})}{P_s} = 1 - \frac{\overbrace{P_{DF} + P_{B\&S}}^{\text{Bearing \& Seals}}}{P_s} \quad (d)$$

$$P_{DF} = \frac{C_m}{2} \rho \Omega^3 r_2^5 \quad (e)$$

Disk Friction

$$\text{Where (for two sides of disk) } C_m \approx 0.085 \left/ \left(\frac{\Omega r_{t,2}^2}{\nu} \right)^{0.2} \right. \quad \text{Typically } C_m = 0.004 \quad (\text{at } Re = 4.3 \times 10^6) \quad (f)$$

\uparrow
 Re

Shaft Power

$$P_s = \frac{\rho g \Delta H}{\eta_p} = \frac{\psi Q_s \rho \Omega^3 r_{t,2}^5}{\eta_p}$$

\downarrow

$$Q_s = \frac{Q}{\Omega r_{t,2}^5} = \Omega_s^2 \psi^{3/2} \Rightarrow P_s = \frac{\Omega_s^2 \psi^{5/2}}{\eta_p} \rho \Omega^3 r_{t,2}^5 \quad (g)$$

Combining the usually smaller $P_{B\&S}$ with P_{DF} , Eq. (d) (with e, f and g) becomes

$$\eta_m = 1 - \frac{(C_m/2) \times \eta_p}{\Omega_s^2 \psi^{5/2}} \quad (h)$$

C) Volumetric Efficiency

From Eq. 11,

$$\eta_v = \frac{Q}{Q + Q_L} \approx \frac{1}{1 + 5 \left[\frac{\frac{\delta}{r_R} \left(\frac{r_e}{r_2} \right)^2}{\Omega_s^2 \psi} \right]} \quad (j)$$

The clearance ratio δ/r_R is typically 0.001 to 0.002

[Leakage back to impeller inlet across two rings (front and back) essentially doubles the leakage loss, changing the value 5 in Equation (j) to 10.]

inviscid solutions⁴², each on a surface of revolution generated by one of the meridional streamlines of the hub-to-shroud 2D solution and producing results like that of Figure 17. From this, one computes the diffusion factors (Eqs. 57–59) and decides whether the diffusion losses are significant—in which case a redesign is in order, followed by a further Q3D evaluation. This type of iterative design approach for impeller blading has led some designers to combine Q3D analysis with an “inverse” design approach and a performance prediction scheme as discussed in this subsection. Here, in distinction to the more common “direct” choice of the conformal blade shape (Figure 19) between inlet and outlet as

described in paragraph (e) (vi) under “Designing the Impeller,” one specifies the distribution of fluid dynamical quantities from inlet to outlet—such as UV_θ or W —and finally produces the corresponding blading^{17,43}. In this sense, specifying W_g as described in the same paragraph (e) (vi) is an inverse design procedure.

Mechanical efficiency η_m as stated earlier, is largely the result of impeller disk friction. If the drag of bearings and seals is added, as in Eq. (d) of Table 3, the moment coefficient C_m in the disk friction formula (e) can be increased over known disk friction values^{44,45} to include these effects. (On the other hand, the drag power loss of shaft seals, though usually quite small, is generally directly proportional to speed. Such losses can therefore be significant in small pumps running at lower-than-normal speeds.) The C_m -expression given in Formula (f) reflects this adjustment and includes the drag on both sides of a smooth impeller for a typical clearance ratio $s/a = 0.05$, where a is the disc radius. This works well for most impellers: The drag at the ring fits roughly compensates for the fact that the impeller eye has been cut out of the disk, and so on. (There is very little influence on C_m of the gap width s between impeller shroud and casing wall, C_m being proportional to $(s/a)^{0.1}$ in general⁴⁴. For very small s/a , C_m instead grows as s/a decreases; see Refs. 44 and 45 for formulas.)

The value of C_m can be even larger for semi- or fully-open impellers, if the neighboring fluid is rotating faster relative to the wall—as is the case with radial-bladed open impellers. The fluid between a shrouded impeller and adjacent wall, on the other hand, rotates at half speed⁴⁴. (In cases where the impeller surface and adjacent wall are both rough, C_m is larger than just discussed⁴⁵.) Finally, notice in Eq. (h) that very low specific speed Ω_s produces a dramatically low value of η_m . This drives ψ to the larger values of Figure 12 at low Ω_s —also dictated by the W -deceleration considerations per Figure 22. Overall there is a benefit, despite possibly lower η_{HY} [Eq. (a)] due to the consequently greater ψ_i and collector loss.

Volumetric efficiency η_v applies to leakage across impeller shroud rings or “neck rings” and balancing drums. Eq. (j) in Table 3 is an approximation for the leakage across a typical ring of a closed-impeller pump, assuming orifice-type flow at a discharge coefficient of $\frac{1}{2}$, as reported by Stepanoff⁴. Referring to Figure 2, leakage Q_L occurs at $r = r_R$, (r_R being approximately 1.2 times r_c) under a pressure difference across the ring of about $\frac{2}{3}$ that of the pump stage. If the shroud is removed and the open blades are fitted closely to the adjacent wall, as with open impellers, the consequent leakage from one impeller passage to the next across the blade tips does not affect η_v , and Eq. (j) should be modified accordingly. Rather, the tip leakage causes a hydraulic efficiency loss as previously discussed. Finally, as with η_m , Eq. (j) indicates that low- Ω_s pumps have low η_v .

At flow rates Q other than Q_{BEP} , the analytical methods described previously for computing the hydraulic efficiency are utilized, together with computation of the inlet and outlet velocity diagrams, which yield the ideal head and power curves as illustrated in Figure 6. In this procedure, the slip velocity V_s (Figure 15) applies to the BEP and, at other flow rates, the exit relative flow angle $\beta_{f,2}$ can be assumed constant. This accords with the fact that V_s for the narrower active jet at low flow rates must be smaller. A blockage model for the thickening wakes and narrower active jets that develop as Q is decreased can be introduced to compute the one-dimensional velocity diagrams, but ignoring this at non-recirculating flow rates appears not to be serious in determining the shapes of the head and power curves.

b) Shut-off and low flow. The foregoing analyses apply over that portion of the flow rate range that does not involve recirculation, as illustrated in Figure 6. The complexity of recirculation has not been readily handled analytically, and this has forced pump designers to estimate the low-flow end of the H - Q curve with the help of empirical correlations. Nevertheless, insightful fluid dynamical reasoning about the physics of the flow have led to useful expressions for the head developed and the power consumed at shut-off. Shut-off, then, in addition to the BEP, becomes the other anchor point of the head and power curves; and this—together with the shapes established for these curves at the higher flow rates—gives the analyst an idea of the intervening shapes.

Shut-off head H_{s_0} can be viewed as the sum of two effects occurring at $Q = 0$, each being represented by a term in this equation:

$$H_{s/o} = \frac{k_{imp} \times (U_{t,2}^2 - U_{h,1}^2)}{2g} + \frac{k_{ex} \times U_2^2}{2g} \quad (65)$$

or

$$\psi_{s/o} = \frac{k_{imp} \times \left(\frac{r_{t,2}^2}{r_2^2} - \frac{r_{h,1}^2}{r_2^2} \right)}{2} - \frac{k_{ex}}{2} \quad (66)$$

where the first term is the centrifugal effect of essentially solid body rotation of the fluid confined within the impeller; and the second term is the pitot effect of the recirculating fluid from the impeller that impinges against the volute or diffuser throats which in turn are connected through stagnant fluid to the exit port of the pump. While the factors k_{imp} and k_{ex} associated with these effects vary with the hydraulic configuration, the values involved can be estimated as follows: $k_{imp} \approx 1$, as the radial equation of motion³ would indicate for fluid rotating at Ωr everywhere within the blades, i.e., for $r_{h,1} < r < r_{t,2}$ (Fig. 8). Thus, as indicated by Eqs. 65 and 66, increasing the minimum radius of the blades at inlet $r_{h,1}$ tends to reduce the shut-off head. However, the presence or absence of fluid swirl in the region upstream of the impeller blades at shut-off has been found experimentally to affect the value of k_{imp} in surprising ways—sometimes increasing it above unity in such a way as to minimize the effect on shut-off head of any non-zero value of $r_{h,1}$. The value of k_{ex} depends on $(r_3 - r_2)/r_2$, or “Gap B” and other features of the impeller exit and collector geometry. It is usually in the range 0.2 ± 0.1 , any change in the geometry that increases the shut-off power coefficient (see below) raising k_{ex} by driving more recirculating flow from the impeller against the volute or diffuser throats. Thus the shut-off head coefficient $\psi_{s/o}$ (Eq. 66) for typical radial-flow pumps generally exceeds $\frac{1}{2}$, the value of 0.585 being advanced by Stepanoff⁴. Estimates for $\psi_{s/o}$ are also indicated in Fig. 22b.

Shut-off power consumption $P_{s/o}$ includes disk, bearing, and seal drag power P_D and that which drives the recirculation P_{recirc} . The latter is generally dominant by far. From similarity arguments (Eq. 33), the shut-off power coefficient

$$\hat{P}_{s/o} = \frac{P_{s/o}}{\rho \Omega^3 r_2^5} \quad (67)$$

is a constant for a given pump geometry. Mockridge, in a discussion attached to an ASME paper by Stepanoff, reasoned that a wider impeller (larger b_2 at the same diameter D_2) would recirculate more fluid at shut-off and therefore have a higher value of this coefficient. His correlation is shown in Figure 23 and is probably the most significant quantitative result available for predicting the performance of centrifugal pumps at shut-off conditions³⁶.

c) Complete prediction via CFD. The uncertainties that have characterized the prediction of pump performance are now being overcome through advances in computational fluid dynamics. CFD entails three-dimensional solution of the flow fields within pumps via the Reynolds-averaged Navier-Stokes equations. Graf demonstrated the ability of a CFD computer code to calculate recirculation, the consequent prediction of the head curve for the impeller comparing favorably with experimental data⁴⁶. The resulting distorted flows entering and leaving adjacent systems of impeller blades and stator vanes produce time-varying boundary conditions on each, the associated computational grids also moving relative to each other. This involves extensive, time-dependent computation. To provide solutions quickly on conventional, storage- and speed-limited workstations, some steady-flow codes treat these interfaces by circumferentially averaging the conditions at each point of the blade and vane leading and trailing edges as they appear in the meridional plane. Even with this simplification, pump analysts can now predict the entire performance curve of head within about two percent and the power curve with slightly less accuracy⁴⁷.

FIGURE 23 Shut-off power coefficient

The design task therefore resolves itself into an iteration between an efficient geometry-generating scheme and a rapid CFD flow and performance analysis of the geometry resulting from each iteration⁴⁸. This is especially useful if a non-traditional geometry is involved, or if an efficient design is sought that will produce a desired performance curve shape. Nevertheless, many turbomachinery designers can make more rapid and valid judgments about their respective classes of machines through the time-honored iteration between a proprietary direct or inverse design and performance-prediction scheme and inviscid quasi-3D analysis^{41,43}. They have developed reliable diffusion criteria (computed, for example, from Eqs. 59a and 59b) for interpreting the acceptability of the free-stream relative velocity distributions W_s and W_p on the blade surfaces (Figure 17) produced by the Q3D blade-to-blade solutions⁴³. Because CFD codes solve the actual viscous flow field, the boundary condition on the blade surface is zero relative velocity. This can be at least partly overcome by displaying the CFD-distributions of pressures on the blade surfaces, the interpretation of which would require knowledge of the corresponding criteria for these pressures⁴⁶. Also, the velocities at the edge of the boundary layer could be extracted from the CFD solution and displayed in familiar terms. A useful design approach for the present may therefore be to a) produce the final design by the more traditional methods and b) predict the performance curves via CFD⁴⁹.

Predicting Axial Thrust The prediction of pump performance is not truly complete without the corresponding prediction of the hydrodynamic axial and radial thrust that the impeller(s) can be expected to encounter. A comprehensive treatment of radial thrust appears in Section 2.3.1, and a review of axial thrust and thrust balancing devices is cov-

ered in Section 2.2.1. However, obscure flow phenomena can profoundly affect the radial distributions of pressure on the outside surfaces of a shrouded impeller that give rise to the net axial thrust. These phenomena become even more complex when discharge recirculation occurs and can cause adverse mechanical response in high-energy pumps, as will be explained further on. As a basis for tackling such problems, the fundamentals of axial thrust are presented in Table 4 for shrouded centrifugal impellers that have leaking fluid flowing in the gaps between the impeller shrouds and the adjacent casing walls. The positive direction of the thrust T is taken toward the suction or eye of the single-suction impeller shown. The incoming axial momentum $\rho Q V_{z,1}$ is generally quite small for radial impellers and has been omitted from the Table. It serves, however, to reduce T .

The centrifugal effect of the fluid spinning in the sidewall gaps causes a reduction in static pressure from the outer periphery (OD) of the impeller to the sealing ring, and this

TABLE 4 Leakage effects on axial thrusts

$$\text{Thrust} = (T_B - T_F) n_{\text{stgs.}} - T_{\text{slv}}$$

$$\text{where } T = \int_{r_{\min}}^{r_{\max}} 2\pi r p dr$$

$$\text{where } p = p_2 - \int^2 \frac{\rho}{g} \frac{V_{\theta, \text{gap}}^2}{r} dr$$

and p and $V_{\theta, \text{gap}}$ are determined as follows in the absence of vanes in the gap:

A) For zero leakage flow, fluid outside impeller rotates at

half speed; i.e., at $\frac{\Omega r}{2}$; namely, $V_{\theta, \text{gap}} = \frac{\Omega r}{2}$; so that

$$p_o - p_i = \int_i^o \rho \frac{V_{\theta, \text{gap}}^2}{r} dr = \frac{\rho \Omega^2}{4} \int_i^o r dr = \rho \frac{\Omega^2 (r_o^2 - r_i^2)}{8}$$

or

$$p_o - p_i = \frac{\rho}{8} \Omega^2 r_o^2 \left[1 - \left(\frac{r_i}{r_o} \right)^2 \right]$$

$$\left[\begin{array}{l} \text{Note: This is } 1/4 \text{ of what } (p_o - p_i) \text{ would be if} \\ V_{\theta, \text{gap}} = \Omega r \text{ (full wheel speed - as on the front)} \\ \text{side of a semi-open impeller)} \\ \text{then, one gets } (p_o - p_i) = \frac{\rho}{2} \Omega^2 r_o^2 \left[1 - \left(\frac{r_i}{r_o} \right)^2 \right] \end{array} \right]$$

B) For non-zero leakage

1) Inflow: $V_{\theta, \text{gap}}$ averages to be $>$ half speed

\Rightarrow greater $(p_o - p_i)$ than at half speed (or zero leakage)

2) Outflow: $V_{\theta, \text{gap}}$ averages to be $<$ half speed

\Rightarrow nearly constant pressure from $(p_o - p_i)$

TABLE 4 Continued.

Specifically,

$$\text{where } V_{\theta, \text{gap}} = \begin{cases} \Omega r_2 \times f_{\text{inflow}} \left(\frac{r}{r_2}, \Phi_{\text{lkg}} \right) \times f_{\text{width}} \\ \text{or} \\ \Omega r \times f_{\text{outflow}} \left(\Phi_{\text{lkg}} \right) \times f_{\text{width}} \end{cases}$$

$$\text{where } \Phi_{\text{lkg}} = \frac{Q_{\text{leakage}}}{\Omega r_2^3} \Rightarrow \begin{cases} \text{Interaction of} \\ \text{leakage and} \\ \text{pressure at ring} \end{cases}$$

$$\text{where } Q_{\text{leakage}} = f_L \left(\ell, \delta, \Omega, v, \Delta p_{\text{ring}} \right)$$

$$f_{\text{inflow}} = \left(0.5 - \frac{450}{\pi} \left| \Phi_{\text{lkg}} \right| \right) \frac{r}{r_2} + \frac{450}{\pi} \left| \Phi_{\text{lkg}} \right|$$

$$f_{\text{outflow}} = 0.5 - 100 \left| \Phi_{\text{lkg}} \right|$$

$$f_{\text{width}} = \frac{\sqrt{A^2 + A} - A}{0.5}$$

$$\text{where } A = 1/[5 \text{ s/r}_2]$$

is quantified in the expressions given for the swirl velocity component V_θ . These expressions are curve fits to experimental data for the leakage flowing radially inward on either or both sides of the impeller⁵⁰ and for outflowing leakage as occurs on the back side (away from the “front” or suction side) of multistage pump impellers due to the higher pressure arising from the diffusing system downstream of each impeller⁵¹. In the absence of leakage, the fluid in the sidewall gap rotates at about half the local impeller wheel speed; that is, $V_\theta = \Omega r/2$, and this half speed is typical of the gap flow near the impeller OD, even in the presence of leakage. The greater the inflow leakage, the lower the pressure becomes at the entrance to the ring clearance. The major effect is that of swirl or the tangential component of velocity V_θ , which varies inversely with radius unless casing wall drag interferes. More leakage flow is less influenced by this drag and so experiences a greater centrifugal effect. This in turn means more pressure drop from OD to ring. (The leakage rate, of course, is affected, the solutions for both leakage and pressure distribution being linked and usually requiring iteration.) The opposite effect happens for outflow on the back side of multistage pump impellers. Here the fluid enters the sidewall gap at a small radius (see Section 2.2.1) and so with negligible swirl. It flows outward without picking up much swirl, especially if there is substantial radial outflow leakage, which means the centrifugal effect is small, yielding a nearly constant pressure versus radius. The overall result is more net thrust than might be expected from a cursory look at the pressure-loaded surfaces.

If wear ring clearances increase during the life of the pump, the net thrust of multistage pump impellers increases. Likewise, unequal ring wear leads to uncertain changes in the thrust of a “balanced” single- or double-suction impeller with inflow to wear rings on both sides. Similarly, these theories can be applied to balancing drums and other such devices described in Section 2.2.1.

Integration of the pressure equation in Table 4 becomes a chore unless the whole theory is computerized. A quick estimate of the thrust is possible, however, if the distributions of pressure in the separable domains of the surfaces are assumed to be linear; in that case,

TABLE 5 Approximate axial thrust calculation

$$\text{THRUST} = F_7 + F_6 + F_5 + F_4 - F_3 - F_2 - F_1 - F_{m,I} + F_{m,II}$$

For Const. - p Forces: $F_j = p_j \times 2\pi (r_{j,o}^2 - r_{j,i}^2) \quad j = 1, \dots, 7$
 $i = \text{inner}; o = \text{outer}$

For Linear $p(r)$ Forces: $F_j = F_{j,\text{const.}} + F_{j,\text{var}}$

$$\text{where } F_{j,\text{var}} = \frac{1}{3} \pi r_{j,o}^2 \left[2 - \frac{r_{j,i}}{r_{j,o}} - \left(\frac{r_{j,i}}{r_{j,o}} \right)^2 \right] \times (p_{j,o} - p_{j,i})$$

Example:

$$F_3 = p_{i,3} \times 2\pi (r_{o,3}^2 - r_{i,3}^2) + \frac{1}{3} \pi r_{3,o}^2 \left[2 - \frac{r_{3,i}}{r_{3,o}} - \left(\frac{r_{3,i}}{r_{3,o}} \right)^2 \right] \times (p_{o,3} - p_{i,3})$$

the integration is simple and yields the closed-form results of Table 5. This table also indicates how to account for each element of the thrust, including the axial momentum terms, which become significant for higher-specific-speed mixed-flow impellers. In all cases, in order to proceed with the calculation, the static pressure at the impeller OD must be known, as it is from the boundary condition imposed at the OD that the rest of the pressure distribution emerges. Even for substantial leakage, the pressure drop of the fluid entering the sidewall gaps from the impeller exit is small or negligible; therefore, the impeller pressure essentially applies in the gap (at the OD) as well. The foregoing methods of predicting pump head also yield the impeller OD pressure, which is usually between 75 and 80% of the stage pressure rise above inlet.

Thrust computations can therefore be coupled with the head-curve prediction scheme being employed for the pump, thereby yielding predicted thrust curves together with the predictions of hydraulic performance.

Ensuring Stable Performance The ability for a pump to run smoothly with minimal pressure-rise and flow-rate excursions is dependent on the shape of the pump head-flow performance curve and the characteristics of the system in which it operates. There are two types of pump-system instability; namely, a) static instability, which can be ascertained by studying the pump and system head curves, and b) dynamic instability, which requires more detailed knowledge of the system⁵². (In addition to these system-related instabilities, there is the unsteady behavior of the separated and recirculating flows that occur when a pump operates a flow rate substantially below the BEP. Called hydraulic instability, this becomes important in higher-energy applications and is therefore discussed later.)

a) Static stability and instability. Figure 24 illustrates two pumping systems; namely, a) a piping system in which the flow is turbulent and largely independent of Reynolds number; so, the head drop ΔH through it is proportional to Q^2 , and b) two reservoirs with a constant difference ΔH between the two liquid surfaces and comparatively negligible head loss in the pipes connecting them. In each case, the pump is designed to produce head ΔH , as required to deliver the desired flow rate Q . The influence of the pump head curve shape is immediately appreciated in Case (b): the curve “droops” as Q is reduced to shut-off, thereby producing two vastly different flow rates at the same head. In fact, however, the pump will not operate at the lower- Q intersection point of the two curves. The pump shut-off head is less than ΔH , so it will produce no positive flow rate. Instead, as discussed in Section 2.3.1, fluid will flow backwards through the pump. Further, if circumstances could allow operation at this lower- Q point, even a vanishingly small increase of Q would cause a further, divergent increase because the head of the pump exceeds the ΔH of the system. Likewise, a small decrease leads to even lesser Q because the system ΔH exceeds that of the pump. This is called “static instability.” Conversely, the higher- Q point of Figure 24b is “statically stable,” small departures in Q being suppressed by algebraically opposite signs of the difference between the system and pump heads. Both intersection points of Figure 24a are seen by this type of analysis to be statically stable. If the operator increases the frictional resistance by closing up a valve in the piping system, the operating point simply moves to the left on the curve and remains stable. Thus, it is concluded that if the slope of the pump H-versus- Q curve is *less* than that of the system, operation will be *statically stable*—and vice versa.

Most pumping systems are combinations of the “pure friction” type of Figure 24a and the “purely elevation” type of Figure 24b. In this case of static stability, the drooping pump head curve presents no problem. Theoretically, it is possible to have a pump head curve with a kink that could have a more positive slope than that of a system curve, which might intersect it at such a kink. The high- Ω_s curve of Figure 22b depicts a kink or dip, which is due to stalled flow within a mixed- or axial-flow impeller that is not sufficiently confined by the impeller to be maintained in solid body rotation. (It is the centrifugal effect of such rotation that maintains the pressure rise in radial-flow impellers despite the stalling.) That particular pump, if applied to a system that never intersects the pump head curve at the kink, would never experience static instability. On the other hand, the designer may want to take on the challenge of designing a machine without such a kink. The previously mentioned design procedure utilizing CFD in both the impeller and the diffuser to check whether the kink is gone would be a way of tackling this problem⁵³.

In-depth discussion of the variety of systems that can be encountered, including multiple systems and parallel operation of multiple pumps, can be found in Sections 2.3.1, 8.1, and 8.2. Purely from a static stability standpoint, most of these situations demand a substantially negative slope of the head curve throughout the range of flow rate Q —or what is commonly specified as a pump with head “continuously rising to shut-off.” (This “rise in head” versus a drop in Q should not be confused with the pump developed head H , which is also properly termed the “head rise” ΔH , produced by the pump at a given value of Q .)

b) Dynamic instability. If the system has appreciable capacitance, operation may not be stable if the slope of the pump head curve is positive or even zero⁵⁴. This is true even though the slope of the pump head curve is less than that of the system head curve as required above for static stability—as with the lower- Q intersection point of Figure 24a. Dynamic instability can be manifested as pump surge, a phenomenon wherein the flow

a) System with frictional resistance only

b) System with elevation change only

FIGURE 24A and B Pump-system stability

rate oscillates and can even be alternately positive and negative through the pump⁵⁴. This is characteristic of "soft" systems that contain vessels with free surfaces and, therefore, appreciable capacitance. Two-phase flow increases the capacitance of a system and can cause dynamic instability. For example, fluctuating vapor volume within the propellant pump inducers can contribute to the dynamic instability of a rocket propulsion system⁵⁵.

On the other hand, a "hard" piping system with no capacitance is theoretically capable of accommodating a pump that has a flat or drooping head curve and that operates on that flat or drooping section of the curve. Low-specific-speed pumps can have drooping curves (Figure 22b), especially if designed with a high head coefficient ψ at the BEP. Figures 5 and 7 of Section 2.3.1 depict flat and drooping curves of low- Ω_s radial-bladed pumps, a type that is widely used in low-cost, small sizes. If properly applied, such machines will operate with stability. On the other hand, a conservative approach that guarantees both static

and dynamic stability for the widest range of applications is to design all pumps without flat spots or droops in the head curves.

DESIGN EXAMPLE

To illustrate the application of the preceding design information, the basic hydraulic design requirements are presented in Table 6 for a single-stage centrifugal water pump with a volute collector. The chosen conditions compute to a universal specific speed Ω_s of 1 ($N_s = 2733$, and $n_q = 52.9$ from Eqs. 38a and 38b). The pump is to be designed for a suction specific speed Ω_{ss} of 4.5 ($N_{ss} = S = 12,300$ by Eqs. 41 and 42), therefore, a “performance-NPSH” (see NPSH discussion in Section 2.3.1) or $NPSH_{3\%}$ of 14 ft (4.27 m). As such, this pump is readily applicable to taking water from an atmospheric reservoir with some suction lift. Although acceptable for 1780 rpm specified for this pump, this suction-specific speed Ω_{ss} of 4.5 is regarded as high for pumps with more head (energy level) than this one (see the energy-level discussion later).

Impeller Design

SUCTION NOZZLE Beginning upstream, an ideal, axial-flow approach passage is assumed —this is known as an “end-suction” configuration. The suction-approach passage or suction branch (not shown) is simply a conical nozzle that increases the velocity of the fluid from the suction port to the impeller eye by about 50 percent in an axial distance of about half the diameter of the eye. This helps to ensure the existence of uniform flow at the eye. Too short a nozzle would mean excessive local meridional (axial in this geometry) velocity at the impeller shroud and possible separation.

IMPELLER INLET Beginning with Ω_{ss} of 4.5, computations for this example are carried out in Table 7 for the impeller eye geometry. The choice of the $NPSH_{3\%}$ correlation of Table 1 is used, with $k_1 = 1.69$ and $k_2 = 0.102$. The local maximum velocity at the eye $V_{1,sh} (= V_{m,1,sh})$ is assumed to be 25% greater than the one-dimensional average $V_e = Q/A_e$. This is smaller than the bladeless result of Figure 14, but is typical of this end-suction configuration,

TABLE 6 Given conditions for design example (single stage, end-suction volume pump)

$$\Omega_{ss} = 4.5 = \frac{\sqrt{\pi \phi_e \left(1 - \frac{r_s^2}{r_e^2} \right)}}{(\tau/2)^{3/4}} \quad (\text{from Eq. 50})$$

$$\text{For } \tau = (1.69 + 0.102) \phi_e^2 + 0.102$$

$$\phi_e = 0.29 = \text{eye flow coefficient}$$

Eye dia/2 = eye radius:

$$r_e = \sqrt[3]{\frac{Q}{\Omega \pi \phi_e \left(1 - \frac{r_s^2}{r_e^2} \right)}} = \sqrt[3]{\frac{2500 \text{ gpm} / 449 \frac{\text{gpm}}{\text{ft}^3 / \text{sec}}}{\frac{\pi}{30} \times 1780 \times \frac{\pi}{\text{sec}} \times 0.29}} \quad (\text{from Eq. 49})$$

$$[r_s = 0 \text{ (no shaft in eye)}]$$

$$r_e = 0.3201 \text{ ft. (0.0976 m)}$$

$$r_e = 3.84 \text{ in. (97.6 mm)}$$

$$\begin{aligned} V_e &= 17.3 \quad (5.3) \\ &= \phi_e U_e \\ U_e &= 59.6 \text{ ft/sec. (18.2 m/s)} \\ &= \Omega r_e \end{aligned}$$

$$(\text{See Fig. 25): } R_{sh} = \frac{r_e - r_s}{2} = 1.92 \text{ in. (48.8 mm)}$$

Other dimensional data shown on Fig. 25.

including the effect of the blading. Moreover, the value of k_1 should be more than adequate for this value of $V_{1,sh}$.

The Ω_{ss} and τ - ϕ_e relationships yield the eye flow coefficient ϕ_e , which in turn sizes the eye. $\phi_e = 0.29$ implies a τ -value of 0.253, which is typical. However, lower ϕ_e - and τ -values are common, especially for the case of a shaft through the eye, because this tends to maintain the level of Ω_{ss} in the face of the r_s -effect in Eq. 50. The nominal velocity diagram at the eye—substantially the shroud-end or tip of the blade leading edge—shows V_e rather than $V_{1,sh}$ for the meridional component of velocity and so is not the actual velocity diagram at that location. Rather, this triangle serves to identify the geometry through the basic ratio $\phi_e = V_e/U_e$ —without having to deal with the uncertain choice of $V_{1,sh}/V_e$. Moreover, ϕ_e is the tangent of the tip relative flow angle $\beta_{f,1}$ as it would be for a uniform axial velocity profile in the eye.

With the eye radius r_e established, the local shroud radius of curvature R_{sh} follows from the guidelines associated with Figure 13. The geometry established so far is illustrated in Figure 25. Before the full picture shown there can be established, the outlet must be sized.

IMPELLER OUTLET The computations in Table 8 for the impeller exit begin with the choice of the typical value of $22\frac{1}{2}$ degrees for the outlet blade angle $\beta_{b,2}$. This enables the head coefficient ψ to be chosen under the guidance of the upper curve in Figure 12. The value 0.385 is selected, and this yields the impeller diameter of 12 in. (304.8 mm). The other curve in Figure 12 is for outlet flow coefficient $\phi_{i,2}$, which conveniently equals 0.1715 for

FIGURE 25 Impeller hub and shroud profiles (design example)

$\Omega_s = 1$. This leads to the exit width b_2 after adding in the leakage and the blockage of blades and boundary layers per the computations of Tables 9 and 10.

However, Anderson⁶ points out that what matters for centrifugal pump performance is neither the blade angle nor the exit width individually, but the impeller outlet relative area $2\pi r_2 b_2 \sin \beta_{b,2}$. Choosing a higher blade angle is possible if b_2 is correspondingly reduced (and $\phi_{t,2}$ increased) so as to maintain this area and therefore the relative velocity W . Figure 15 shows that $V_{\theta,2}$ is thereby essentially unchanged; this in turn preserves the impeller head.

EFFICIENCIES Anderson's overall pump efficiency correlation (Figure 10 and Eq. 44) and the component efficiency expressions of Table 3 lead to the results of Table 9. These give an indication of the relative magnitudes of the losses and are as follows:

Overall efficiency $\eta_p = 0.8550$

Mechanical efficiency $\eta_m = 0.9814$

Volumetric efficiency $\eta_v = 0.9833$ (leakage across front and back rings)

Hydraulic efficiency $\eta_{HY} = 0.8860$

η_{HY} is at this point simply deduced from the others, beginning with Anderson's correlation. Although it is confirmed by Jekat's correlation in the table, it can be found in a

TABLE 8 Impeller outlet (design example)

From Figure 12

$$\beta_{b,2} = 22 \frac{1}{2}^\circ \rightarrow \phi_2 = \frac{V_{m,2}}{U_2} = 0.1715 \quad (= \phi_i)$$

$$\rightarrow \psi = \frac{g_0 \Delta H}{U_2^2} = 0.385$$

$$(U_2 = \Omega r_2) = \frac{\pi}{30} \times 1780 \times \frac{6}{12} = 93.2 \frac{\text{ft.}}{\text{sec.}} (28.4 \text{ m/s})$$

$$r_2 = \sqrt{\frac{g \Delta H}{\Omega^2 \psi}} = 12 \sqrt{\frac{32.174 \times 104}{\frac{\pi^2}{30^2} \times (1780)^2 \times 0.385}}$$

$$= 6 \text{ in. (152.4 mm) [12 in. (304.8 mm) dia.]}$$

$$\text{Width: } b_2 : A_2' = \pi D_2 b_2'$$

$$b_2 = b_2' + 2\delta_0^* + \text{Leakage Effect}$$

Solve after obtaining volumetric efficiency and getting approximate passage length (to compute δ_0^*)

detailed computation of the hydraulic losses via one-dimensional methods. This will be carried out further on to obtain the performance characteristic curves. Meanwhile, this initial computation enables the determination of $V_{\theta,2}$ at the end of Table 9, which, along with $V_{m,2}$ from Table 8, is a major element of the outlet velocity diagram of Figure 26.

BLOCKAGE AND WIDTH AT IMPELLER EXIT With the leakage and exit blade angle information, Table 10 contains the computations of the blockage and the exit width b_2 . This entails the choice of the number of blades, the blade thickness t (2% of the impeller diameter and typically assumed to exist at the exit and elsewhere on the blades except near the leading edges where typically half that value is chosen), and the approximate blade length ℓ (assuming the mean-streamline blade angle to be constant at $22\frac{1}{2}$ deg). The boundary layer blockage is computed from the following approximations:

- Adverse pressure gradients on the blades lead to a boundary layer displacement thickness δ^* of twice the zero-pressure gradient value δ_0^* on each blade surface.
- Secondary flows scrub the boundary layers from the hub and shroud surfaces; so, δ^* is assumed to be equal to δ_0^* on those surfaces.
- $\delta_0^* = 0.0462 \ell^{0.8} \nu^{0.2} / W^{0.2}$ for flat-plate, turbulent flow⁵⁶, and is approximated in this example for low viscosity by a linear growth with length along the blade.

The resulting thickness of the boundary blockage is 0.0732 in (1.86 mm) on the blades, which themselves have a thickness of 0.24 in (6.1 mm). Because these thicknesses are inclined at the $22\frac{1}{2}$ -deg outlet angle, the actual circumferential blockage is $(1 - \varepsilon_{2,b}) = (1 - 0.870)$ or 13 percent of $2\pi r_2$. In particular, $(0.24 + 0.0732)/\sin(22\frac{1}{2} \text{ deg}) = 0.82$ in or (6.1

TABLE 9 Component efficiencies (design example)

$$\text{Efficiency: } \eta_p = 0.94 - 0.08955 \left(\frac{2500}{1780} \right)^{-0.21333} - 0.29 \left[\log_{10} \left(\frac{2286}{2733} \right) \right]^2 = 0.8550$$

(Eq. 44)

$$\text{Mech. Eff'y: } \eta_m = 1 - \frac{0.002 \times 0.8550}{1^2 \times (0.385)^{5/2}} = 0.9814 \quad [P_D = 1.43 \text{ hp. (1.07 kW)}]$$

(from Table 3)

$$\text{Volumetric Efficiency: } \eta_v = \frac{1}{1 + 5 \frac{0.0016 \times (3.84/6)^2}{1^2 \times 0.385} \times 2} = 0.9833$$

(from Table 3)

$$\text{Hydraulic Efficiency: } \eta_{HY} = \frac{\eta_p}{\eta_v \eta_m} = \frac{0.8550}{0.9650} = 0.886 \quad \text{vs.}$$

(Eq. 8)

(Jekat's formula in Table 3):

$$\eta_{HY} \approx 1 - \frac{0.8}{(2500)^{0.25}} = 0.887$$

$$\Rightarrow V_{\theta,2} = \frac{32.174 \times 104}{93.2 \times 0.886} = 40.5 \text{ ft/sec.}$$

$$\Rightarrow \psi_i = \frac{40.5}{93.2} = 0.435$$

+ 1.86)/sin(22½ deg) = 20.8 mm per blade, which for all six blades is 0.130 times the circumference of 37.7 in (958 mm). The width b_2 is computed to maintain $V_{m,2}$ at the chosen value of $0.1715 \times U_2$, while accommodating this blockage and that of the sidewall boundary layers. Altogether, it can be computed from these data that 85 percent of the meridional exit area $2\pi r_2 b_2$ is estimated to remain open for the one-dimensional flow of $(Q + Q_L)$ at velocity $V_{m,2}$, the boundary layers causing ⅓ of the blockage. This is quite typical. An openness of 90 percent is possible for larger impellers.

HUB-SHROUD PROFILES It is now possible, through the guidelines outlined in the discussion of Figure 13, to finish plotting the hub and shroud profiles in Figure 25, which are also seen in Figure 26c. At this point, the envelope of the leading edges of the blades is approximated by a circular arc—later modified somewhat in the construction of the blades. The arithmetic average radius of the meridional passage at the leading edges is found with the circle of diameter 2.85 in (72.4 mm) to be 2.72 in (69.1 mm). The resulting line passing through the center of the circle is normal to both hub and shroud and is approximated by the dashed straight-line leading-edge quasi-normal shown in the Figure 26c.

INLET VELOCITY DIAGRAMS The rms radial point on this quasi-normal line of Figure 26c crosses the leading edges of the blades at $r_{1,\text{mean}} = r_{1,\text{rms}} = 2.91$ in (73.9 mm) and is slightly larger than the arithmetic average radius of 2.72 in (69.1 mm). It is this latter radius that

TABLE 10 Impeller blade blockage and width at exit (design example)

$$b_2 = 0.0366 + \frac{2500 \times 0.3208 / 0.9840}{\underbrace{0.1715 \times 93.2}_{V_{m,2}} \times \underbrace{0.870}_{\varepsilon_{2,b}} \times \pi \times 2 \times 6} = 1.59 \text{ in. (40.4 mm)}$$

(Since

$$b_2 = 2\delta_o^* + \frac{Q + Q_L}{V_{m,2} \times \varepsilon_{2,b} \times \pi \times 2 \times r_2})$$

**FIGURE 26A through C** Impeller velocity diagrams for design example: a) inlet; b) outlet; c) meridional view

must be used in computing the one-dimensional meridional velocity. After obtained, it is applicable to the rms location (the location of the “mean” or “rms” inlet velocity diagram). This diagram is one of three triangles shown for the inlet in Figure 26a, the other two being located at the hub and shroud locations of the blade leading edges. Notice that $V_{m,1}$ for the rms triangle is 16.3 ft/sec (5.0 m/s), which is slightly less than the eye velocity V_e of 17.3 (5.3). Allowing for blade blockage, this would bring the blocked meridional velocity V_m within the blading closer to V_e , the objective being to keep V_m constant in the inlet region and turn into the radial direction. The other triangles correspond to the radial locations of the blade at hub and shroud, as illustrated in Figures 26c and 27, and assume that $V_{m,1,sh} = 1.25$ times $V_{m,1}$, and $V_{m,1,h} = 0.75 V_{m,1}$. A full Q3D solution would determine these velocities more accurately; however, the design usually proceeds in this way—largely because the hub blade angle is usually a good deal larger than hub flow angle. Efforts to match the hub flow angle more closely entail special blading that is beneficial for high-energy pumps but has little effect otherwise. The blade angle at the shroud is slightly lower than the flow angle (by about 1 deg). This slightly negative incidence is actually ideal for efficient flow and minimum cavitation. The largest values of U and W exist at the shroud, as can be seen for the shroud inlet triangle, making it important to have the best match at that point. Two deg positive incidence is quite common at the mean or rms radial location and allows for blockage by the blades that does not increase the relative velocity W as the fluid enters the impeller.

OUTLET VELOCITY DIAGRAM The outlet velocity components having been found in Tables 8 and 9, the slip velocity V_s must still be found in order to obtain the complete outlet velocity diagram shown in Figure 26b. This slip is computed by Pfleiderer’s method (Table 2), which utilizes the $r(m)$ shape of the mean meridional streamline illustrated in Figure 27, V_s emerging as 15% of U_2 . The “ a ” factor for influence of the collector geometry was taken in the middle of the range for volutes at 0.75; (see Table 2). Wiesner’s Eq. 52 yields 17.65%. This would mean 6% less $V_{\theta,2}$ and head. However, this discrepancy is not unexpected, and in view of the earlier discussions on slip, the Pfleiderer result is chosen as more realistic.

Nevertheless, uncertainty in the slip is the Achilles heel of the one-dimensional analysis method. For this reason, most analysts “calibrate” their codes by deducing the slip from test results and applying it to impellers of similar geometry. For Pfleiderer’s method, this would be done by calibrating the “ a ” factor. CFD solutions now appear to be the best approach to overcoming this difficulty.

As has been emphasized heretofore, this outlet velocity diagram contains the basic information about the performance and design of the pump. It supplies the boundary conditions for the volute design, but first the impeller blading that must produce it will be established and evaluated.

IMPELLER BLADING As indicated in Figure 26, the blade angles at both inlet and outlet have been chosen at hub, mean, and shroud (with the same $22\frac{1}{2}$ deg all across the trailing edge being assumed, although some would specify a little variation). Fitting a reasonable blade shape between these end conditions can be done in the conformal plane (illustrated in Figure 19). These shapes, when transformed as described earlier, yield the hub, mean, and shroud blade shapes identified in the polar view of Figure 28. In actuality, the inverse “point-by-point” method was used, specifying W_s as indicated in Figure 29 and, at each of the 21 stations along the mean line of Figure 27, developing the velocity diagrams in the manner employed to arrive at Figure 26b; obtaining β_b at each station; and developing the *mean-streamline blade shape* of the polar view with Eq. 60. Involved in this procedure—which was computerized—was the calculation at each station of the blockage and of the local slip velocity, the latter being estimated as a fraction of the discharge slip velocity V_s that increases rapidly to unity as the exit is approached.

Note that the meridional area is needed at each station in order to compute V_m . As indicated in Figure 27, this is approximated here as the area of the frustum of a cone defined by the dashed lines or “quasi-normals,” which are as nearly perpendicular to both hub and shroud as possible. Except for some machines with meridionally curved passages and a large passage width-to-length ratio causing the true normals to be strongly curved, the quasi-normal approach works well.

Description of the pressure side of the blade

FIGURE 27 Impeller blading—meridional view (design example)

To establish the *blade shapes along the hub and shroud*, the corresponding “grid lines” of Figure 19 were found from polynomials satisfying the end conditions of blade angle and location, the y -position of the inlet end of the grid line being iterated until the desired blade wrap was obtained. In this way, different wrap angles $\Delta\theta (= \theta_2 - \theta_1)$ can be imposed, but a tolerable resulting blade shape requires that these $\Delta\theta$ s be not much different from the $\Delta\theta (= 119.1^\circ)$ obtained on the mean line from the method just described. In this example, it was possible to maintain $\Delta\theta$ the same on all three construction lines. Alternatively and perhaps more consistently, the inverse approach could be applied at hub and shroud as well as on the mean line.

Regardless of which procedure is used to generate the hub, mean and shroud blade shapes—the conformal transformation method, the point-by-point method, or some combination—the *shape of the blade everywhere else* still needs to be established. To do this, the shapes of the constant- θ lines in Figure 27—called “blade elements”—must be specified. This can be done mathematically as indicated on the figure or by eye (the latter approach is widely used). Note that each constant- θ line actually lies in a different meridional plane. Thus, Figure 27 depicts a superposition of all 21 meridional planes, each containing an intersection of the blade surface and appropriately identified as having the θ -value noted on the figure.

DIFFUSION ASSESSMENT Figure 29 is a presentation of the free-stream relative velocity distributions at the blade surfaces and halfway between. The rapid approximate method of

FIGURE 28 Impeller blading—polar view, showing pressure sides of the blades (design example)

Stanitz (Eq. 54) is utilized to obtain the surface W 's, the mean values of W on the mean (rms) streamline coming from the local velocity diagrams developed at each station²². The mean W 's at hub and shroud are found at the ends of the respective constant- θ lines under the assumption that the ideal head or UV_θ -product is constant along each of these lines from hub to shroud. This is usually a fair approximation; however, a Q3D analysis (Figure 14) would yield a closer estimate of these mean W -distributions^{16,41}. Nevertheless, the diffusion factors computed from the plotted surface velocities by means of Eqs. 59 are shown on the figure—these values are well below the 0.6 limit. This would indicate that the resulting solidity of 1.48 (originally estimated at 1.46 in Table 10) is adequate, and that the correct number of blades was chosen.

Notice also on Figure 29 that the exit value of W is significantly larger than W_g , which is consistent with the outlet velocity diagram of Figure 26b. Further, a slight jump in the mean W at the inlet is indicated; however, as the higher value of W is not sustained, it is

FIGURE 29 Blade surface relative velocity distributions (design example)

unlikely that it actually occurs in the 3D velocity field. Moreover, details near leading and trailing edges are not well handled by Eq. 54—a 2D blade-to-blade solution is more desirable for this type of diffusion assessment⁴².

Volute Design With the exit velocity V_2 of 43.6 ft/sec (13.3 m/s) and the tangential velocity component $V_{\theta,2}$ of 40.5 ft/sec (12.3 m/s) from Figure 26b, the volute design process is started in Table 11 using Eq. 61. This entails a choice of the radial "Gap B" of 6% of the impeller radius r_2 and a tongue leading edge thickness t_t equal to 70 percent of the impeller blade thickness. These choices are not critical for a pump of low energy level such as this is, as the stresses imposed by the flow on structural elements are small. The throat area A_T is then found to be 32.60 in² (21,032 mm²) and the throat velocity V_T computes to 24.60 ft/sec (7.50 m/s), which is 56% of V_2 and so represents considerable diffusion from impeller exit to throat. (The throat area A_T is the fundamental feature of a volute and acts in concert with the impeller exit area, as emphasized by Anderson⁶ and Worster²⁵ and described in the earlier part of this section on *Designing the Collector* in terms of the intersection of the casing and impeller lines²⁶.)

The circumferential *distribution of the volute cross-sectional area* A_v versus polar angle θ_v from the tongue (Figure 20a) is developed in the latter part of Table 11, a final listing being presented for a) linear A_v versus θ_v and b) constant one-dimensional angular momentum $r_v V_v$. This listing illustrates an earlier statement that the latter approach pro-

TABLE 11 Volute casing (design example)

Refer to Fig. 20

A) Throat area A_T

Simultaneously solve for A_T from

$$\text{a) } r_T \frac{Q}{A_T} = 0.95 r_2 V_{\theta,2} \quad (\text{Eq. 61, using 0.95}) \quad \text{since } A_T = \frac{Q}{V_T}$$

and

$$\text{b) } r_T = r_3 + \frac{1}{2} \sqrt{A_T} + t_t \quad (\text{Fig. 20, assuming a square throat})$$

Eliminating r_T in combining (a) and (b) yields a quadratic equation in $\sqrt{A_T}$:

$$\text{c) } A_T \times \left(\frac{0.95 r_2 V_{\theta,2}}{Q} \right) - \frac{1}{2} \sqrt{A_T} - (r_3 + t_t) = 0$$

Taking $r_3 = 1.06 r_2$ (i.e., “Gap B” = $0.06 r_2$), $r_3 = 6.36$ in (161.5 mm); assuming $t_t = 0.7 t_b = 0.7 \times 0.24 = 0.168$ in. (4.3 mm); and using consistent units in (c); leads through the quadratic formula to

$$A_T = 32.60 \text{ in}^2 (21,032 \text{ mm}^2)$$

Thus $V_T = 24.60 \text{ ft/sec (7.50 m/s)}$

B) Cross-sectional area

If volute cross-sectional area A_v is distributed linearly vs. θ_v , A_v and the radius r_v to the center of the cross section are as follows:

$$\text{d) } A_v = A_T \frac{\theta_v(\text{deg})}{360} = \frac{32.60}{360} \times \theta_v \text{ in}^2 = \frac{21,032}{360} \times \theta_v \text{ mm}^2$$

$$\begin{aligned} \text{e) } r_v &= r_3 + \frac{1}{2} \sqrt{A_v} = 6.36 + \frac{1}{2} \sqrt{A_T (\text{in}^2)} \quad \text{in} \\ &= 161.5 + \frac{1}{2} \sqrt{A_T (\text{mm}^2)} \quad \text{mm} \end{aligned}$$

If A_v is found subject to constant angular momentum with $r_v V_v = 0.95 r_2 V_{\theta,2}$,

$$\text{f) } A_v = \frac{Q}{V_v} \times \frac{\theta_v(\text{deg})}{360} = \frac{Q \left(r_3 + \frac{1}{2} \sqrt{A_v} \right)}{0.95 r_2 V_{\theta,2}} \times \frac{\theta_v(\text{deg})}{360}$$

TABLE 11 Continued.

This is a quadratic equation in $\sqrt{A_v}$, which, when solved, gives the results for "constant $r_v V_v$ " in the listing below, r_v being found from Eq. (e) for both this and the linear case.

Volute cross sections (design example)

| θ_v deg | Linear A_v vs. θ_v | | | | Constant ($r_v \times V_v$) | | | |
|-------------------|-----------------------------|-----------------|--------|---------|-------------------------------|-----------------|--------|---------|

* $r_v = r_3$ at $\theta_v = 0$
 ** transition to $r_T = 9.38$ in (238.3 mm) and $A_T = 32.6$ in² (21032 mm²) due to tongue thickness

duces smaller areas upstream of the throat than does the former. Frictional effects in the smaller- A_v portion of the volute are less prominent using the linear approach. A CFD assessment at all flow rates can be made to guide the design choice here. Finally, the one-dimensional constant $r_v V_v$ method can be improved upon by integrating a constant $r V_v$ distribution over each cross section, and the proper design must satisfy also continuity²⁶.

Estimated Performance Characteristics Detailed computation of hydraulic losses, together with leakage, disk friction, and other mechanical drags was done as described previously, and the results are presented in Figure 30. The method predicts the pump efficiency to be 85.5% at the design point of 2500 gpm (0.1577 m³/s), peaking at 86 percent at a 5% lower flow rate. The power consumption peaks at the design point at 77 hp (57 kW), indicating that this is a "non-overloading" design; that is, shaft power does not increase beyond this flow rate. The empirical methods reviewed earlier for shut-off head and power were applied here and blended into the one-dimensionally computed curves at half of the BEP flow rate.

The shut-off head coefficient value of 0.596 is close to the 0.585 value of Stepanoff⁴ and is admittedly open to alteration. The rise of head from design point to shut-off is from 104 up to 161 ft (31.7 up to 49.1 m) or 55%. This percentage could be smaller and still ensure stable operation in any typical system; however, the non-overloading feature could change, the power peaking at a higher flow rate. In retrospect, the design-point head coefficient ψ of 0.385 could be larger without the diffusion-factor results of Figure 29 becoming excessive. One would conclude from this exercise that the ψ -curve of Figure 12 is conservative and could be higher. Of more significance, however, is the demonstration in this design example of the utilization of easily applied fundamental fluid dynamical analyses such as the diffusion assessment illustrated in Figure 29 as the basic arbiters of design choices such as the head coefficient, number of blades, and so on. Furthermore, the shapes of the performance characteristics are revealed.

FIGURE 30 Estimated performance characteristics (design example)

The shut-off power is 34 hp (25 kW), arising from a power coefficient of 0.047 from Mockridge's correlation³⁶ for a b_2/D_2 of $1.59/12 (= 40.4/304.8) = 0.1325$ —as found from Figure 23. This is 44% of the design-point power, a typical result. As seen in Section 2.3.1, this percentage increases with specific speed, where, of course, b_2/D_2 is also larger³⁶.

The $NPSHR (= NPSH_{3\%}$ for this example) at off-design conditions is estimated empirically. At the higher, non-recirculating flow rates, $NPSHR$ is related to the head required to accelerate the relative velocity within the blades to values higher than at the design point¹⁴. As stated in Section 2.3.1, operation at $NPSH_{3\%}$ involves performance in the presence of extensive internal two-phase behavior. This is complicated by recirculation at the lower flow rates. Therefore, the full $NPSHR$ curve in such a case usually has to be established experimentally.

HIGH-ENERGY PUMPS

Over the past few decades, there has been a trend toward pumping machinery that concentrates more power within a given volume. This trend is driven by cost and technology improvements. The basic energy transfer relationships show that smaller size demands higher rotative speed. Thus, over the same time period, speeds of high-power pumps have been increasing. Moreover, the number of stages in multistage pumps has been decreasing. There have been spikes in these trends; the resulting pumps suffering from excessive vibration, rotor and hydraulic instabilities, component failure, and cavitation damage⁵⁷. The term “high energy” has been applied to these machines, and this label can be quantified in terms of the stresses arising in critical pump components and the likelihood of an adverse mechanical response that such stress levels imply. Research has led to technical solutions for effectively controlling rotordynamic behavior and reducing unsteady hydraulic thrust and surge as well as cavitation erosion^{53,58,59}. The resulting pump reliability improvements and life extension should enable the previous trends to continue. Being aware of the energy level enables the pump user to assess whether operation and maintenance difficulties are likely to occur after the pump is installed and running, and it enables the designer to take the appropriate measures to ensure the technical integrity of the product.

Pressure Pulsations Measured at the inlet or outlet port, the amplitude of the pressure pulsations can be a significant fraction of the pressure rise of the pump—especially at flow rates well below that of the BEP for the speed involved. Sources are a) the interaction of the pressure fields of the impeller and diffuser or volute, b) unsteady separated and reversed flows at impeller inlet and discharge and in the diffuser, c) cavitating flows, and d) combinations of these phenomena. Pressure pulsations presumed to exist at the impeller OD from the interaction of impeller blade-to-blade and diffuser vane-to-vane variations of pressure have been calculated by inviscid flow analysis to have a peak-to-peak amplitude that is of the same order as the static pressure rise of the impeller⁶⁰. Moreover, the viscous, thicker wakes existing at lower-than-BEP flow rates (here called “low flows”) and separated recirculating fluid from both impeller and diffuser that participate in these interactions can be expected to increase the pressure pulsation amplitude at such conditions.

Figure 31 confirms these ideas, showing a bronze impeller that operated extensively at low flow. Cavitation pitting can be observed near the OD of the impeller, which means that the rarefactions of the pressure waves were below the vapor pressure of the liquid—these pressure minima therefore being below the inlet pressure to the impeller. Moreover, the bulged-out shrouds can be assumed to be the result of the repeated occurrence of the associated pressure spikes (that is, the maxima of the pressure waves) within the radial gap (“Gap B”) between the impeller blades and the diffuser vanes, the sidewall pressures on the outsides of the shrouds remaining comparatively constant. At greater values of design pressure rise than was the case for this impeller, this phenomenon creates correspondingly greater forces that have led to actual breakage of the impeller shrouds and diffuser vanes⁶¹. The cavitation seen in Figure 31, can also be observed on the leading edges of diffuser vanes, as in Figure 21 of Section 9.5, and this raises the possibility of diffuser vane breakage.

Energy Level: Stage Pressure Rise Even in the absence of the weakening effect of cavitation erosion, the leading edge of a diffuser vane or volute tongue is a representative, highly stressed zone within a pump that is subject to failure if the magnitude of the pressure pulsations arising from the impeller-diffuser interactions just described is sufficiently large. Thus, the hydraulically induced stresses in these vanes can be the basis for quantifying the energy level of a pump stage. In Table 12, this concept is developed into an expression for the stress in terms of the fluctuating pressure magnitude δp that is assumed to act across the vane leading edge as illustrated in the table. The width b of the vane is close enough to b_2 of the impeller exit to utilize the relationships for ψ and ϕ_1 of Figure 12 to relate b/D to specific speed in Eq. (c) of the table. For similar velocity fields, the pressure pulsation magnitude δp is a constant multiplied by the stage pressure rise ΔP_{stg} . Thus, for a limiting value of stress, the concept of a limiting stage pressure rise

FIGURE 31 Damage to impeller from low-flow operation (Source: E. Makay in *Power*)

emerges in Eq. (e). The constant K is chosen from experience, which leads to the resulting Eq. (f). This relationship is plotted in Figure 32. [It will be observed that this choice for K corresponds to a limiting stress s from Eq. (d) of 6,600 psi (45.5 MPa) that would exist if δp were equal to ΔP_{stg} —with $t/D = 0.01$ and $\varepsilon = 0.85$ as in the example.] The inverse variation with specific speed is a consequence of the greater b/D of higher- Ω_s pumps (as developed in Table 12), the wider vane introducing more stress at the juncture with the sidewalls for the same pressure loading and so imposing a lower stage pressure-rise limit. Conversely, lower- Ω_s pumps should have higher limits for ΔP_{stg} .

Figure 32, therefore, illustrates this concept of a *limiting stage pressure rise* as a measure of the energy level of centrifugal pumps, the basis being a limiting stress level in a critical component of the pump. Starting with stress at other locations in the pump leads to similar results. To provide perspective, specific examples of pumps that by this definition are in the *high-energy domain* are plotted on the figure. These data points are taken from Table 13, which contains information for several well-known liquid rocket engine turbo pumps^{62,63,64} and for some representative high-energy electric utility boiler feed pumps^{53,57}.

The last column in Table 13 is another, more general way of comparing the energy level of these machines; namely, the *torque per unit volume*, which also has the dimensions of stress. For fixed ratios of stage width, casing OD, and other dimensions to impeller radius r ($= r_2$), torque per unit volume differs from the listed values of torque/r^3 by a factor. The actual torque per unit volume therefore ranges from one-half to one-sixth of the tabulated

TABLE 12 Hydraulically induced stress levels

- Stress at juncture of diffuser vane leading edge with sidewall:

$$s = \frac{\delta p b^2}{2t^2} = \frac{(\delta p/2)(b/D)^2}{(t/D)^2} \quad (a)$$

- From Fig. 12 and Eq. 36:

$$\frac{b}{D} = \frac{Q}{V_{m,2} 2\pi r_2 \varepsilon D} = \frac{Q}{\Omega r_2 \frac{V_{m,2}}{\Omega r_2} 4\pi r_2^2 \varepsilon} = \frac{Q_s}{\phi_i 4\pi \varepsilon} \quad (b)$$

- From Eq. 50:

$$\frac{b}{D} = \Omega_s^2 \psi^{3/2} / (4\pi \phi_i \varepsilon) \quad (c)$$

- With $\psi \approx 0.383/\Omega_s^{1/3}$ and $\phi_i \approx 0.1715\sqrt{\Omega_s}$

the stress Eq. (a) becomes, with Eq. (c)

$$s = \frac{\delta p \times \Omega_s^2}{165 \times (t/D)^2 \varepsilon^2} \quad (d)$$

- Example for $t/D=0.01$, $\varepsilon=0.85$, $\Omega_s=0.6$ and $\delta p=1000$ psi (6.895 MPa):

$$s = \frac{1000 \times (0.6)^2}{165 \times (0.01)^2 \times (0.85)^2} = 30,198 \text{ psi (208.2 MPa)}$$

- For δp being proportional to ΔP_{stg} , and for a fixed geometry and a given limiting value of stress, Eq. (d) becomes

$$\Delta P_{\text{stg}} = K/\Omega_s^2 \quad (e)$$

- Experience leads to a choice of K such that

$$\Delta P_{\text{stg}} = \frac{78.72}{\Omega_s^2} \text{ psi} = \frac{0.5427}{\Omega_s^2} \text{ MPa} \quad (f)$$

torque/ r^3 , depending on the casing or barrel thickness, and so on. However, as has been demonstrated, the critical stresses are more closely associated with the impeller OD, which makes comparison of the tabulated values more relevant. Thus, a pump with high torque/ r^3 can be expected to have correspondingly high local internal stresses. The maximum values listed, namely for the high-pressure propellant pumps on the RD-170 (Russian) and SSME (U.S. Space Shuttle) engines, tend to explain the high level of research and development that was necessary to successfully deploy these machines. Illustrations of some of these rocket engine pumps can be found in Section 9.19.2. Similarly, Section 9.5

FIGURE 32 Pump energy level defined in terms of stage pressure rise

provides examples of high-energy boiler feed pumps: the massive, barrel-type construction of these machines is illustrated in Figure 18. Specifically, the first boiler feed pump listed in Table 13 is the sole feed pump supplying the steam generator of a super-critical 1300 MW electric generating unit and consumes nearly 50 MW of shaft power. It can be seen in Figures 7 and 20 of Section 9.5.

For pumps in the *low-energy domain* of Figure 32, normal design and manufacturing practices result in a more benign mechanical response to the abnormal fluid phenomena discussed here. However, for locations other than the diffuser entrance, which was the basis for the development of the figure, limiting stresses could be reached at considerably lower values of stage pressure rise. For this reason, the dashed line is offered as the upper limit of the low-energy domain; however, a thorough analysis of the stresses in any given application is the ultimate determinant of all the limits suggested in Figure 32 and of the acceptability of the design. It can now be seen that the design example treated earlier in this section is of the low-energy variety; therefore, the special design problems treated here and further on are of relatively little concern in such pumps. On the other hand, if the curve in Figure 32 were extended to much *higher specific speeds*, it would be found that many existing, large, high- Ω , low-head pumps are high-energy machines by this stress-related definition. It is therefore not surprising that such pumps generally require full stress and modal analyses to identify possible destructive resonances and stresses.

Fluid/Structure Interactions With the dimensions of pump energy level identified, the next step is to continue the examination of the problems mentioned previously and the methods that have become available for solving them. Attention is focused on hydraulic phenomena because, as the previous discussion of pressure pulsations implies, most of the adverse mechanical behavior exhibited by pumps originates from the behavior of the internal flow field. Excessive measured vibrations, material erosion, and component failures are often the external symptoms of fluid/structure interaction phenomena that are fundamentally explained from a hydraulics perspective. In addition to the hydraulically

TABLE 13 Data on high-energy pumps*

| Pump | No. of stages | Speed rpm | Flow rate gpm (m ³ /s) | Head/stg ft (m) | ΔP /stg psi (MPa) | Specific Spd N _s (Ω _s) | Torque/r ³ psi (MPa) |

*Notes to this table: Flow rates apply to the pump inlet. RD-170 pump data derived from Sutton⁶² and Advanced Class boiler feed pump data from Ref. 57. Remaining data derived from Table 1 of Section 9.19.2, NASA reports^{63,64} and from information supplied by Flowserve Corporation.⁶³

induced stresses in the pump structure that culminated in the domain definition of Figure 32, these phenomena encompass a) blade-vane interactions, b) recirculation, c) anomalous axial thrust behavior, and d) cavitation.

In order to illustrate the methods for dealing with the problems created by these fluid/structure interactions, a sample suction stage of a high-energy multistage pump is utilized as the quantifying focus in each case. Table 14 contains the conditions and essential features of this machine, a meridional view of which is shown in Figure 33. As with the earlier design example, this stage has been designed in accordance with the procedures outlined for that example. This includes the velocity diagrams shown in the figure, as well

TABLE 14 Data for high-energy pump suction stage

A. Design Inputs

| | |
|--|----------------------|
| Fluid: Boiler feed water at 350°F (177°C) \Rightarrow sp. gr. = 0.89, ν = 0.17 cs. | |
| Flow rate, Q , gpm (m^3/s) | 20,000 (1.262) |
| Head rise, ΔH , ft (m) | 3,000 (914.4) |
| Rotative speed, N , rpm | 4,700 |
| Outlet flow coefficient, ϕ_2 (Figure 12) | 0.1328 |
| Head coefficient, ψ (Figure 12) | 0.455 |

B. Calculated Performance Data

1. Efficiency

a) BEP of 20,000 USgpm (1.2618 m^3/s)

$$\eta = \eta_p = 0.877 \quad (\text{vs. } \eta=0.8682 - \text{from Fig 10, for } X=1)$$

$$\eta_{hy} = 0.900$$

$$\eta_m = 0.985$$

$$\eta_v = 0.989 \quad [216 \text{ gpm } (0.0136 \text{ m}^3/\text{s}) \text{ front ring leakage; rear ring leakage included in } \eta_{hy}]$$

b) At 50% Flow : $\eta_p = 0.693$ (= 0.79 of η_{BEP} ; 0.8 is typical)

2. Head Rise

$$\Delta H_{BEP} = 3000 \text{ ft. (914 m)} \Rightarrow \psi = 0.455$$

$$\Delta H_{shutoff} = 3697 \text{ ft. (1127 m)} \Rightarrow \psi_{s/o} = 0.560$$

$$\Delta H\text{-vs-}Q \text{ curve stability indicator, } \Delta H_{s/o}/\Delta H_{BEP} = 1.23 \text{ (doubtful if less than 1.2)}$$

3. Power

$$P_{s,BEP} = 15,376 \text{ hp (11,466 kW)} \sim \hat{P} = 0.0571$$

$$P_{s,SHUTOFF} = 6,144 \text{ hp (4,583 kW)} \sim \hat{P}_{s/o} = 0.0228 \quad (= 0.01966 \times 1.16 \text{ from Fig. 23})$$

 $= K \text{ for } \frac{b_2}{D_2} = 0.0779$

as the design of the eye, the hub and shroud profiles, and the blading. A preliminary design was also made of the vaned diffuser and return vanes, following the guidelines presented in the foregoing *Design Procedures* subsection. The result is a representative machine to which the following paragraphs continually refer.

Blade-Vane Combinations Certain numerical combinations of impeller blades and diffuser vanes (or inlet guide vanes, where they are employed) have been shown to have acoustic consequences that can exacerbate the pressure pulsations arising from the interaction of impeller and diffuser flow fields. Bolleter reviewed the types of interactions that can occur and the consequences with regard to pressure pulsations and resonance³³. These

FIGURE 33 Sample suction stage of high-energy multistage pump

types are associated with the integer difference m between the multiples of the number of impeller blades and the number of diffuser vanes, as explained in Table 15. To check the blade-vane combination, one simply forms a matrix of the multiples as shown and lists the difference in each cell.

To illustrate the method, rather than use the pump of Table 14, a different example is chosen in order to dispel the notion that one can always use two different prime numbers for blade-vane combinations. This is an existing case of a 60,000 *hp* (45 MW) single-stage pump of $\Omega_s = 0.6$ ($N_s = 1640$) and $\Delta p = 357 \text{ psi (2.46 MPa)}$, which has 7 impeller blades and 13 diffuser vanes⁶⁵. Notice that $m = 1$ in the second order of impeller blade number, which means there should be pressure pulsations at $2 \times 7 \times \text{rpm}/60 \text{ Hz}$. In fact, this pump has exactly this vibration and pressure pulsation frequency in the field, not least because the pump is operating at just the right speed for the acoustic waves emanating from successive interaction points to reinforce each other in producing unacceptable pressure pulsations.

Even with this simple method, the final choice of the blade-vane combination is usually a compromise. For example, the method shows that all double-volute pumps have $m = 0$ or 1 in the first order of impeller blade number, depending on whether this number is even or odd. $m = 0$ means that all the blades or vanes are interacting at the same instant, a consequence of which is torque ripple. High-energy volute pumps exist for both even and odd cases—quite large gaps between blades and vanes (= “Gap B”) are employed to mitigate these effects.

The reader who checks the pump of Table 14 by this method will find that $m = 2$ in the first order of both blades (7) and vanes (9) but that $m \neq 0$ everywhere else in the matrix.

TABLE 15 Choosing vane combinations to minimize pressure pulsations³³

1. Z_i is the number of impeller blades.
2. Z_d is the number of diffuser vanes.
3. Each vane combination produces interacting pressure fields between the blade rows.
4. These fields form “m” rotating “nodal diameters”, producing unsteady loads
5. The value of “m” determines the nature and severity of these loads.
6. “m” is the difference between $(p \times Z_i)$ and $(q \times Z_d)$, where p and q are integers.
7. To find “m”, one sets up a matrix of diffuser vanes and their multiples vs. impeller blades and their multiples or “orders”. A minimum of the first three orders should be used. This is illustrated as follows for an impeller with 7 blades ($Z_i=7$) and a diffuser with 13 vanes ($Z_d=13$):

| | | Impeller blades and their multiples: | | | |
|-------------------------------------|--------------|---|-----------|-----------|-----------|
| | | p=1 7($=Z_i$) | p=2 14 | p=3 21 | p=4 28 |
| Diffuser vanes and their multiples: | | Differences “m” between $(p \times Z_i)$ and $(q \times Z_d)$ are give below: | | | |
| q=1 | 13($=Z_d$) | 6 | 1 | 8 | 15 |
| q=2 | 26 | 19 | 12 | 5 | 2 |
| q=3 | 39 | 32 | 25 | 18 | 11 |

The significant values of “m” are 0, 1 and 2. The lower the order of either the impeller blades or the diffuser vanes, the stronger is the interaction. The responses that occur for these “m” values are as follows:

- $m = 0$ - strong pressure pulsations and fluctuating axial loads and torsional forces.
- $m = 1$ - pressure pulsations and fluctuating radial loads.
- $m = 2$ - small pressure pulsations and a chance of resonance of the impeller about the two nodal diameters - at a frequency equal to the value of $q \times Z_d$ times the rotational frequency (rpm or rps)

In this example, $m = 1$ in the second order of the impeller blades (i.e., $p=2$); thus, the frequency of the resulting disturbances will be twice that of blade passing frequency $p \times Z_i \times \text{rpm}$ or $2 \times 7 \times \text{rpm}$ cycles per minute or $2 \times 7 \times \text{rpm}/60$ Hertz. This is therefore a poor vane combination and should be avoided - especially for such low orders of vane number; i.e., for such small values of p and q. (Here, $p=2$ and $q=1$.) In general, $m = 0$ and 1 should be avoided altogether, and $m = 2$ should be avoided in the lower orders.

$m = 1$ occurs only in the highest orders of both and should therefore be of little consequence. Checking whether 10 or 11 vanes would be better yields $m = 1$ in the third order of impeller blades and second order of diffuser vanes, which is probably less desirable than $m = 2$ in the first orders. Therefore, Figure 33 shows a value of “Gap B” that is 12 percent of the impeller radius, which should provide adequate protection from pressure pulsations and excitations of resonance. (The gaps at the impeller OD will be discussed further on.)

Recirculation Separation and stall of the fluid flowing in the passages of impellers and diffusers occurs at low flow because of the incidence and large reduction in the one-dimensional velocity relative to the passage that happens at low flow. This and the con-

sequent recirculation patterns in the impeller were discussed and illustrated in Figure 6. Fischer and Thoma⁶⁶ visually observed and recorded the flow patterns, finding that as flow rate is reduced, wakes on the suction side of all blades thicken until they occupy half the passage width at half the BEP flow rate. At lesser flow rates, the wakes continue to thicken but become irregular, stalling in one passage and not the others—the stall pattern moving into and out of adjacent passages and so rotating relative to the impeller. As shut-off is approached, this rotating pattern is accompanied by reversed flow emerging from the inlet of the stalled passage. Fraser, working with typical impeller geometries, formulated rules for computing the flow Q_{SR} at which this reversal occurs as Q is reduced at constant speed⁶⁷. His expressions, found further on, include the effect of impeller eye size on Q_{SR} . As one might expect, a pump with an eye diameter approaching that of the impeller OD will have Q_{SR} approaching Q_{BEP} . At $Q < Q_{SR}$, the impeller flow patterns are highly unsteady—as is usually the case with massively separated flows—creating non-synchronous, low-frequency or random pressure pulsations, the resulting shear layers between the reverse-flowing and in-flowing fluid having vortices with locally low pressures so cavitation can also exist. Fraser also quantified the flow rate Q_{DR} below which impeller discharge recirculation exists. Forces from such motion can cause fatigue failure of the impeller blades, diffuser vanes or volute tongue, cavitation erosion also playing a part as in Figure 31. In Section 2.3.2, Fraser describes the identification and consequences of recirculation in detail, the more general designation Q_R referring to either Q_{SR} or Q_{DR} , depending on whether Q is between or below both.

The ability for pumps to operate with any form of separation; stall; or, worse, flow reversal (recirculation) depends on the energy level. This can be approximately quantified, as outlined under the subject of *Minimum Flow Limits* further on, which include consideration of accompanying cavitation activity.

Axial Thrust Response to Recirculation Discharge recirculation usually involves backflow from the diffuser, itself containing oscillating flow patterns and rotating stall. Fluid emerging from the diffuser will be spinning opposite to the direction of rotation, such fluid having a major effect on the sidewall gap flows as it joins the leakage flows described under *Predicting Axial Thrust*. As this fluid invades the sidewall gaps, it can slow or virtually cancel the usual positive swirling of the gap fluid. Iino, Sato, and Miyashiro experimentally observed and recorded this behavior, which was exaggerated by shifting the impeller axially and by changing the ring clearances⁶⁸.

An added, not unexpected effect is that as Q is reduced below Q_{DR} , the invading flow from the diffuser can favor the front or back side of the impeller and then *switch sides* upon further reduction of Q . This effect is clearly seen in the experimental thrust-versus- Q plots of Figure 34, the impellers having been shifted as just described. Depicted there is the resulting net load on the axial thrust bearing of an eight-stage, 3600-rpm diffuser pump that had a cylindrical balancing drum (not a self-compensating balancing disk). The drum was sized so as not to completely eliminate the thrust—in order to avoid thrust reversals. The solid lines are the predicted net thrust according to the methods outlined in Table 4 for three axial positions of the impeller. The large excursions in net thrust were eliminated by restricting the entry of the invading diffuser backflow into the sidewall gaps—through a tightening of the gap between the shrouds of impeller and diffuser (Gap “A”) in Figure 35. Gap “A” is not effective unless the “overlap” of the two mating shrouds is from four to six times the gap dimension⁶¹. Moreover, if Gap “A” is minimized, this can exaggerate the blade-vane interactions, making it necessary to open up Gap “B” more than would be necessary were Gap “A” not minimized⁶⁹.

A further possibility that has been observed in a single-stage double-suction pump is the *unsteadiness* of impeller discharge recirculation and, most likely, of the diffuser or volute backflow. The side-to-side switching just mentioned appears in Figure 36 to be happening as a function of time as well as of flow rate Q , as evidenced by the axial motion, which is accompanied by discharge pressure pulsations. The “fix” mentioned in the figure was, again, mainly minimizing Gap “A.”

Closing Gap “A” and opening Gap “B” are procedures that have been widely and successfully applied in high-energy pumps, which usually work well at BEP but run into difficulties at low flow⁶⁹. The procedures have proven to cure the thrust and pressure

FIGURE 34 Axial thrust response to recirculation. (Source: Flowserve Corporation)

pulsation behavior just described and also improve the low-flow performance curve shape⁶⁵. The results are high-energy pumps that can operate smoothly over a wider range of flow rate than—in many cases—was originally expected or specified. Nevertheless, the higher the energy level, the more intolerable is any unsteadiness and pressure pulsation activity.

Minimum Flow Limits Because the intensity of pressure pulsations and the accompanying vibrations can increase beyond acceptable limits as flow rate is reduced at constant speed below the BEP flow, or more specifically, below Q_R , expressions for how low Q/Q_{BEP} can be without exceeding these limits have been developed. Manufacturer and user groups such as the Hydraulic Institute (HI), the International Standards Organization (ISO), and the American Petroleum Institute (API) have specified vibration limits that must be met at what is usually called the minimum continuous stable flow (*MCSF*) or simply Q_{min} . In an attempt to answer the question of how far into the recirculation zone (where $Q < Q_R$) an operator can take a pump before reaching the *MCSF*, Gopalakrishnan proposed a general rationale for computing Q_{min} that takes the energy level into account—through the flow rate and rotative speed of the machine⁷⁰. These two quantities imply the blade tip speed at the inlet of the impeller. (Through typical ratios of impeller OD to eye diameter, this also implies the OD tip speed and therefore the head, the energy level having been defined in Figure 32 in terms of stage pressure rise Δp_{stg} .) The theory for this method is defined in Part A of Table 16, in which Q_{min} is computed as the product of a series of K-factors multiplying the value of Q_R , which is computed according to Fraser's earlier development⁶⁷. Conceptually, the product of these factors approaches unity in the maximum-energy case, where the instabilities accompanying any recirculation at all are

FIGURE 35 Gaps at impeller periphery⁶¹FIGURE 36 Eliminating unsteady thrust and pressure pulsations (Source: E. Makay in *Power*.)

significant. Conceivably, this product could exceed unity at the highest energy levels, as separation and stall and the attendant unsteadiness must occur—as Q is reduced—before the backflows that characterize Q_R , which was observed by Fraser as the value of flow rate for the onset of recirculation (see Section 2.3.2).

K_1 and K_3 are given in Table 16 as equations that have been curve-fitted to speed/flow rate- and $NPSH$ -effect charts that appeared in Gopalakrishnan's presentation⁷⁰. This includes the ability to enter any speed (rpm) into the computation for K_1 , only 3500 and

1800 rpm having explicitly appeared in the charts. $NPSH$ plays a role in the determination of Q_{\min} —through the factor K_3 —because of the exacerbation of the unsteadiness and pressure pulsations due to dilation of the cavities in the two-phase internal flows that exist for any value of $NPSH$ that is less than the inception $NPSH_i$. (See the ensuing cavitation discussion and the description in Section 2.3.1 that accompanies the definition of $NPSH$ -limits.)

As an example, the minimum flow of the high-energy pump suction stage of Table 14 and Figure 33 is computed in Part B of Table 16. (The value of R for the calculation of K_3 is taken from Table 18.) This machine has the relatively high energy level of some of the boiler feed pumps shown in Figure 32 and listed in Table 13. Thus it is not surprising that the resulting value of Q_{\min} is 90% of Q_R (which equals Q_{SR} , as is typical) and 48.5% of the BEP flow rate. This is indicated on Figure 37, in which the computed performance curves

A) Theory

$$Q_{\min} = Q_R \quad K_1 \quad K_2 \quad K_3 \quad K_4 \quad K_5, \text{ or } Q_R, \text{ whichever is smaller (i.e., product of } K\text{'s} \leq 1)$$

$$Q_R = \begin{cases} Q_{SR} & \text{if } D_e \geq 0.5 D_2 \\ Q_{DR} & \text{if } D_e \leq 0.5 D_2 \end{cases}$$

$$Q_{DR} = \pi D_2^2 b_2 \frac{\Omega}{2} \overline{C_{DR}}$$

$$\overline{C_{DR}} = -0.01 + \beta_{b,2} / 218.75$$

$$Q_{SR} = \pi \Omega r_e^3 \left(1 - \frac{D_s^2}{D_e^2} \right) \cdot \overline{C_{SR}}$$

$$\overline{C_{SR}} = \tan \beta_1 \cdot \left\{ 1 - 0.2091 \cdot (\beta_1 - 9.5)^{0.4} \right\}$$

$$K_1 = \left[0.06862 \times \left(\frac{N - 1800}{1700} \right) \right] + Y + 0.3843 \log_{10} Q$$

$$Y = \begin{cases} -0.4529 & \text{for } Q \text{ in gpm} \\ +1.1612 & \text{for } Q \text{ in m}^3/\text{s} \end{cases}$$

$$K_2 = \text{Specific gravity}$$

$$K_3 = \left\{ \begin{array}{ll} 0.6 + 0.4 \times \left[\frac{1}{3} \left(\frac{4}{R} - 1 \right) \right]^{1.1} & \text{Pump with shaft through eye} \\ 0.7 + 0.3 \times \left[\frac{1}{3} \left(\frac{4}{R} - 1 \right) \right]^{1.1} & \text{End-suction pump} \end{array} \right\} \quad R = \frac{NPSH_A}{NPSH_{3\%}}$$

$$K_4 = \begin{cases} 1 & \text{Continuous operation at minimum flow} \\ 0.7 & \text{Operation at minimum flow less than 25\% of total operating time} \end{cases}$$

$$K_5 = 1 \quad \text{No specific mechanical design margins}$$

TABLE 16 Continued.

B) Results for Sample High-Energy Pump Suction Stage (See Fig. 33)

$$Q_R = Q_{SR}, \text{ since } D_e \geq 0.5 D_2$$

$$Q_{SR} = \pi \Omega r_e^3 \left(1 - \frac{D_s^2}{D_e^2} \right) \cdot \overline{C_{SR}} = \pi \times 4700 \frac{\pi}{30} \times \left(\frac{6.6855}{12} \right)^3 \cdot \left(1 - \frac{2^2}{3^2} \right) \times \overline{C_{SR}} \frac{\text{ft}^3}{\text{sec.}}$$

$$\text{and } \overline{C_{SR}} = 0.3 \cdot \left\{ 1 - 0.2091 \cdot (16.7 - 9.5)^{0.4} \right\} = 0.1618$$

$$Q_{SR} = 24.03 \text{ ft}^3/\text{sec} = 10,785 \text{ gpm } (0.6804 \text{ m}^3/\text{s}) = 0.540 \times Q_{BEP}$$

$$K_1 = 1.317 ; K_2 = 0.89 ; K_3 = 0.768 ; K_4 = 1 ; K_5 = 1$$

$$Q_{\min} = 10,785 \times 0.9002 = \underline{9,709 \text{ gpm } (0.613 \text{ m}^3/\text{s})} = 0.485 Q_{BEP}$$

**FIGURE 37** Estimated performance of high-energy pump suction stage

of this pump are displayed. (See Part B of Table 14 for the main elements of these performance predictions.) However, some of the remedies that have been discussed in this section to counter the adverse effects of high-energy pump phenomena can reduce Q_{\min} to lower values than this. In fact, the method contains the flexibility to take into account such improvements through the factor K_5 .

In computing Q_{SR} , the angle β_1 is called for. This is approximated by the inlet flow coefficient $\phi_e = 0.3$ from Table 14, which corresponds to a nominal inlet tip flow angle of 16.7 deg. The actual flow angle (and blade angle) at that location is slightly larger due to the hub-to-shroud variation of the incoming meridional velocity as assumed in the development of the inlet velocity diagrams of Figure 33. This will have a small effect on the results, depending on how one interprets “ β_1 .” In this regard, as can also be appreciated from the choices that must be made for the K_s , the method of Table 16 is not precise; however, it is a useful indicator of what the user and designer can expect in determining the operating range of a pump.

The above general theory for computing minimum flow is inclusive of all types of centrifugal pumps and has found application especially for high-energy pumps, which can be difficult to evaluate precisely in the varying circumstances of installation and operation in which they are usually applied. The judgments that must be made in order to apply the method of Table 16 can be largely avoided if actual data for Q_{min} are available. It would in fact be a monumental task to establish precise limits for all pump types and operational envelopes. Nevertheless, the effect of energy level on $MCSF$ has been found experimentally for several classes of API process pumps through extensive testing. From this, Heald and Palgrave have developed a method for computing the minimum flow of these pumps as follows⁷¹:

$$Q_{min} = MSCF = \frac{K_7}{100} K_M \times Q_{BEP} \tag{68}$$

where

$$K_7 = K_7(\text{rpm, configuration, } N_{ss}) \tag{69}$$

and

$$K_M = K_M[(NPSH_A/NPSH_R)_{BEP}, \text{ fluid}] \tag{70}$$

Obtained from Figure 38, the factor K_7 accounts for the effects of speed and configuration. As used in that chart—and in Eq. 69, the term *suction-specific speed* N_{ss} (or Ω_{ss})

FIGURE 38 Minimum continuous stable flow (MCSF) for process pumps⁷¹

does not mean that $NPSH$ -effects are also included; rather, this expresses the fact that the impeller design is affected by the designer's choice of N_{ss} as can be seen in the case of the earlier *Design Example*, beginning in Table 6. This leads immediately in Table 7 to the inlet flow coefficient ϕ_e (through the $NPSH$ -correlations of Table 1) and the impeller eye diameter D_e or radius r_e . Following on from the discussion of *Recirculation*, the ratio Q_{SR}/Q_{BEP} can be expected to increase with eye size or D_e/D_2 . Being strictly based on experiments, the Heald and Palgrave method does not deal explicitly with Q_{SR} or Q_{DR} , but one can see from Eq. 38 that this principle is operative: Higher- N_{ss} pumps require greater $MCSF$. Before this fact was clearly understood, the trend was to design for greater N_{ss} —in order to increase suction capability of these pumps. When operators ran them back to the same low flows as they had done with earlier pumps designed for lower- N_{ss} capability, failures became epidemic. This led to a call for "lower-suction specific speed pumps," or, more accurately, pumps designed for lower- N_{ss} capability; specifically 11,000 ($\Omega_{ss} = 4$) or less⁷².

The $NPSH$ -effect does come into play—as with K_3 in the previous general method — through the factor K_M in Figure 39a. In this case, the term $NPSH_R$ means $NPSH_{3\%}$. Here again, it is the ratio $R = NPSH_A/NPSH_R$ that is the determining factor because it is a measure of the cavitation activity that is invariably present in the first stage of a pump, and

FIGURE 39 $NPSH$ -effects on: a) $MCSF$ and b) impeller life⁷¹

therefore in all single-stage pumps. The lower the value of R , the more violent the pressure pulsations accompanying the recirculating fluid and the consequent vibration. The situation is mitigated considerably at greater R , and K_M operates through Eq. 68 to decrease the $MCSF$. Of course, if R were great enough—often 5 or more— $NPSH_A$ would exceed $NPSH_i$ (as discussed in Section 2.3.1) and there would then finally really be no cavitation in the pump. (That high a value of $NPSH_A$ is rare; for, if it were supplied, there would hardly be a need for a pump in the first place.)

Figure 39a also brings in the effect of the liquid being pumped. When room temperature water boils (cavitates), the mass boiled off by the local drop below the vapor pressure makes considerably more cavity or bubble volume than some other liquids, namely hydrocarbons and hot water¹⁷. (See Section 2.3.1.) The table refers to room temperature or cold water.

By way of illustration, computing the minimum flow of the end-suction volute pump of the *Design Example* begins with Curve B in Figure 38 (for pumps with 6-inch discharge and larger and for 1800 rpm and lower as stated on the figure). [This pump has a discharge port of about 9 inches (229 mm) as would be the case if the velocity in this port were half of the throat velocity V_T in Part A of Table 11, as suggested previously in the paragraphs on *Volutes under Designing the Collector*.] N_{ss} for this pump was chosen as 12,300 ($\Omega_{ss} = 4.5$), which yields 41.5% for K_7 . If it were decided to provide this cold-water pump with 16.4 ft (5 m) of $NPSH_A$, R would be 1.17, and the figure yields 0.97 for K_M . [$NPSH_{3\%} = 14$ ft. (4.27 m) for this pump, as seen in Table 6.] Thus, from Eq. 68, this pump has an $MCSF$ of 0.415×0.97 or 40% of Q_{BEP} . Had it been designed for $N_{ss} = 11,000$ ($\Omega_{ss} = 4.025$), and if R still were 1.17, the $NPSH_A$ would have been 19 ft (5.8 m) and $MCSF$ would have been 0.36×0.97 or 35% of Q_{BEP} . Moreover, if it were pumping hydrocarbons at this same $NPSH_A$, $MCSF$ would have been even lower, namely 0.36×0.78 or 28% of Q_{BEP} . It would appear, though, that for many applications, the pump as designed (at $\Omega_{ss} = 4.5$) has a low enough energy level to allow for an adequate range of flow-rate capability, and that therefore, the value $N_{ss} = 12,300$ is in this case not excessive.

Cavitation Considerations Having alluded to and treated the subject of cavitation a number of times in this section, we should expand on the role that this ever-present phenomenon plays in the operation and durability of centrifugal pumps, particularly those having a high energy level. The manifestations of cavitation that are encountered and become issues for the operability and life of a pump are a) cavitation accompanying backflow from the impeller eye, b) cavitation-generated instabilities and pressure pulsations, and c) erosion, which involves the prediction of the $NPSH_R$ -versus-flow rate characteristic curve to maintain life and, conversely (d) the prediction of life for a given $NPSH_A$. The range of $NPSH$ over which cavitation occurs within a pump extends from the point where pump head or pressure rise undergoes an identifiable drop—usually 3% for repeatable results for the $NPSH$ -value involved—namely the “performance- $NPSH$ ” or $NPSH_{3\%}$ —upwards. As $NPSH$ increases from this point, there is an extensive range over which no observable performance loss is detected, yet erosive damage is progressing at a sometimes excessive rate. Finally, at the upper end of the range, all two-phase activity ceases—all bubbles and cavities are suppressed—namely, at the inception- $NPSH$ value or $NPSH_i$. As stated previously, $NPSH_i$ has been observed to be typically about five times $NPSH_{3\%}$. This is clearly described in Section 2.3.1, in which the different $NPSH$ -limits are distinguished. The following cavitation considerations pertain to this range.

a) Cavitation and backflow. The minimum flow limits imposed by the R -value or $NPSH$ -effect arise partly because a lower flow rate at a low $NPSH$ —although it may be in excess of $NPSH_{3\%}$ —involves a strong interaction between suction recirculation and cavitation that can be intense, especially for inducers and large-eye (large D_i/D_2) impellers. At flow rates $Q \ll Q_{SR}$, there exists upstream of the impeller an annulus of back-flowing fluid that emerges from the impeller. Drawing the velocity diagram at the impeller leading edge at the shroud for the case of reversed flow reveals that the absolute velocity component V_i is mostly circumferential and ii) is greater than the impeller tip speed $U_{i,1}$ or U_c . Thus the fluid leaving the impeller hugs the outer wall of the approach passage. If this passage is an axial pipe supplying an end-suction impeller or inducer, the pressure along the centerline can be below the vapor pressure, thus creating a vapor core that extends many

diameters upstream, as was shown in a photograph that is part of an article by Yedidiah⁷³. Obviously the energetic backflow has to be balanced by an equivalent inflow that enters the impeller from the interior of the pipe and therefore along the hub streamline of the impeller. Vapor from the core is drawn in also and tends to fill the impeller and vapor-lock it. At this point, the pressure to drive the highly spinning liquid upstream is non-existent and the backflow ceases. The vapor core disappears and the impeller once more begins ingesting liquid, the process just described repeating itself at a very low frequency (as low as 1 to 6 Hz) and called cavitation surge⁷⁴. It has been found possible to passively divert the backflowing liquid outward from the inlet passage at the impeller or inducer eye into a series of vaned passages surrounding the inlet pipe, the vanes deswirling the backflowing liquid and returning it to a point or annular port upstream. Properly designed, this “backflow recirculator” has completely eliminated all cavitation instabilities in inducers—over the full range of flow rate from shut-off to run-out. It was shown to work for some high- N_{ss} impellers to which it was applied⁷⁴. Cavitation surge, however, is rarely seen in low- N_{ss} impellers and is usually completely avoided by running the pump at flow rates greater than minimum flow Q_{min} as established by one of the previous methods or by test.

b) Cavitation-related instabilities and pressure pulsations. At flow rates greater than Q_{min} , cavitation can cause or intensify pressure pulsations. Such instabilities are connected with the variety of cavity and bubble configurations that can exist over the range of flow rates and $NPSH$ - or R -values. The nature and extent of cavitating flow within a pump has been studied extensively by visual observation. Figures 40 and 41 are laboratory photographs⁶¹ of a sector of a boiler feed pump impeller eye, in which the suction sides of some of the blades are visible. These were taken with the aid of a bright flash that lasted for 1 μs . They can also be found in Ref. 24 of Section 2.3.1. Figure 40a shows the sheet cavity that exists at BEP flow rate and at an R -value of 2. Also observed at BEP—but at $R = 1$ (that is, $NPSH = NPSH_{3\%}$)—is the thick, extensive cavity of Figure 40b. This cavity extends from the blade leading edge to the throat formed by the leading edge of the following blade, and this same pattern exists on every blade. Most observers note that when this suction-side cavity reaches the next throat, the pressure rise or liquid head starts breaking down—which is what is recorded at this “3-percent- $NPSH$ ” point. Instabilities tend to be at a minimum at both of these relatively steady-flow conditions.

Figure 41, on the other hand, displays highly unsteady cavity flows. Both photographs (A and B) were taken at the same half-flow condition at different instants—for $R = 2$. A similar sequence of three photographs at this condition appears in Section 9.5, and none of the three possesses a cavity pattern that resembles either of the others. The position of the somewhat smaller cloud in Figure 41b that has broken off the main cavity appears to be traveling toward the pressure-side (out of sight) of the next blade. Pressure-side cavitation erosion would be the result, and this accords with the findings in Section 2.3.2.

Pressure pulsations are associated with unsteady cavitation patterns, and plots of the amplitude and frequency of suction pressure pulsations show increasing frequency as R is

FIGURE 40 Cavities on impeller blades at BEP flow rate: a) $NPSH = 2 \times NPSH_{3\%}$; b) $NPSH = NPSH_{3\%}$. (Source: Flowserve Corporation)⁶¹

FIGURE 41A and B Cavities on impeller blades at half the BEP flow rate: $NPSH = 2 \times NPSH_{3g}$. (Source: Flowsolve Corporation)⁶¹

increased—as would be expected as bubble size is reduced. The amplitude peaks at R greater than 1—usually closer to 2. Elimination of these instabilities is best done by avoiding cavitation. This can be done by increasing $NPSHA$ and optimizing the blade shape for minimum cavity activity⁷⁵. To avoid the excessive pump and system oscillations that can occur, some users specify that a cavitation-flow visualization test be conducted and require that minimal or no cavities shall be observed.

c) Erosion due to cavitation and the prediction of the Life-NPSH. In the majority of cases cavitation is unavoidable, and the issue becomes the life of component (usually the impeller) in resistance to attack by collapsing bubbles and larger cavities as they are swept out of the low-pressure regions near the blade leading edges. The pressure created at the point and instant of collapse is immense. Photographs of the erosive damage resulting from this activity can be found in Sections 2.3.1 and 9.5. The surface failure mechanism is one of fatigue due to repeated collapse of bubbles adjacent to the blade. This happens at a large number of closely spaced sites, the resulting erosion having a strongly pitted texture. The rate of erosive depth penetration into the surface of a venturi subject to bubble collapse was found by Knapp⁷⁶ to increase as the sixth power of velocity V at a constant cavitation number $k = 2(p_1 - p_v)/\rho V^2$. In other words, the erosion rate increased as the third power of $(p_1 - p_v)$ or $NPSH$ at the inlet of the venturi, which means that the collapse pressure rises with $NPSH$, as is known from the Rayleigh bubble collapse theory. The velocity V in Knapp's venturi corresponds in a pump to the maximum relative velocity W at inlet—which is conveniently represented by the impeller inlet tip speed $U_{t,1}$ as a criterion for damage rate—and τ corresponds to the cavitation number k . For a given impeller at constant Q/N and a constant value of τ , (or at a constant available suction specific speed,) the higher $U_{t,1}$ is, the greater the $NPSH$ and the greater the damage rate. Also, as mentioned earlier, a higher value of $U_{t,1}$ implies a correspondingly greater U_2 and, therefore, greater pump pressure rise or head. Therefore, high-head pumps are more likely to suffer from cavitation erosion, making cavitation a “high-energy” pump phenomenon. High pressure-rise has already been shown to be a feature of high energy pumps through the definition of energy level in terms of classical stress loading (Figure 32).

Facing the reality of high-energy pump destruction due to cavitation erosion, Vlamming redefined the term “ $NPSHR$ ” to mean $NPSH_{40,000 \text{ hrs}}$; that is, the $NPSH$ needed to limit the damage sufficiently so as to ensure an impeller life of 40,000 hours. He developed an empirical method for predicting the curve of this “damage- $NPSH$ ” versus flow rate for conventionally-designed impellers⁷⁷. This method is defined in Table 17 and includes the inlet tip speed effect on the erosion rate. A value of the vaporization factor C_b that is less than unity applies to hot water and to other liquids such as hydrocarbons, which generate far less vapor volume when they cavitate than does cold water. (See the earlier discussion under *NPSH Effects* in the subsection on *Specific Speed and Optimum Geometry*.) (Rather than depend on theory for the API process pumps men-

$$\text{and } X = (S^{1.105} - S)/1000 \quad \text{where } S = \begin{cases} NPSH_{SE}(\text{ft}) \\ 3.2808 \times NPSH_{SE}(\text{m}) \end{cases}$$

tioned earlier in connection with their minimum flow data, Heald and Palgrave quantified $NPSH_{40,000 \text{ hrs}}$ in Figure 39b⁷¹.)

Applied to the high-energy multistage pump suction stage of Figure 33 and Table 14, Vlamming's method yields the $NPSH_R$ -values shown in Table 18 under the heading $\phi_e = 0.3$. These are plotted as the $NPSH_{40,000 \text{ hrs}}$ -curve on Figure 37. The blades of the pump are assumed to be set for zero incidence of the incoming flow to their camber lines at the BEP—called “shockless entry” and denoted by “SE.” (Many designers make Q_{SE} somewhat larger than Q_{BEP} to achieve lower $NPSH_R$ at $Q > Q_{BEP}$.) The column to the right in the table contains the results for the same method applied to the more common case for high-energy pump suction stages, namely $\phi_e = 0.25$ (and lower). For the same shaft diameter, flow rate and speed, $\phi_e = 0.25$ yields a larger eye diameter through Eq. 49; namely, 13.92 in. (353.6 mm) versus 13.37 in (339.6 mm) for the $\phi_e = 0.3$ case as shown in Figure 33. Moreover, that figure shows the inlet tip speed $U_{t,1}$ (U_e) to be 274 ft/sec (84 m/s), whereas for the larger-eye case the value is computed to be 286 ft/sec (87 m/s). As Table 18 reveals, this larger-eye impeller has a lower value of $NPSH_{3\%}$ (as computed from the correlations of Table 1), which is the reason for sizing large eyes. But Vlamming's method indicates that the smaller eye requires less “damage- $NPSH$ ” ($R = 1.69$) than does the larger eye ($R = 2.06$), even though the latter requires less “performance- $NPSH$ ” or $NPSH_{3\%}$. So, from both a minimum-flow and a cavitation damage standpoint, the advantage of a smaller eye for high energy levels is evident.

d) *Prediction of life for a given $NPSH_A$.* The inverse of the foregoing problem is how to determine the life under cavitating conditions at a given value of available $NPSH$. Gülich found a connection between an observed length L_{cav} of the cavity trailing off the leading

*Values predicted for sample high-energy pump suction stage: φ_c = 0.3; φ_c ≤ 0.25 widely typical of suction (1st) stages.

edge of the blade at BEP (Figure 40a) and the life of an impeller operating at this condition⁷⁸. The resulting procedure is outlined in Table 19, beginning with the definition that the life is the time it takes for the erosion to penetrate through 75% of the blade (or wall) thickness. In the absence of a cavitation-visualizing test, *L*_{cav} can be estimated as suggested by the last two formulas in Table 19⁷⁵. Critical to this estimate is the assumed value of the “inception-*NPSH*” or *τ*_{*i*}. For conventionally designed impeller blades, *τ*_{*i*} ≈ 1 at the BEP, whereas aerodynamically shaped blades that minimize the local reduction of static pressure have been produced with *τ*_{*i*} < 0.5 at the BEP^{75,79}. The life computations of Table 20 follow from application of the method of Table 19 to the sample suction stage of Figure 33 for *τ*_{*i*} = 1 and 0.5. Higher values of *τ*_{*i*} apply for *Q* ≠ *Q*_{BEP}—as might be expected from the shape of Vlaming’s *NPSH*_{40,000 hrs.}-curve in Figure 37 and the fact that the local pressure reduction in the leading-edge region increases with incidence. From this and the results of Table 20, it is evident that improvements to conventional blade-design practice are essential if life is to exceed half a year. Further, this life calculation method is based on the existence of a sheet cavity like that of Figure 40a; and the disordered cavity structures of Figure 41, which happen in the presence of recirculation, are not addressed. Low-flow cavitation damage is generally more severe, and is described in Section 2.3.2.

TABLE 19 Prediction of life under cavitating conditions**Table 19.** Prediction of Life Under Cavitating Conditions

Life = the minimum of (Life_{s.s.}, Life_{p.s.}),

where s.s. = suction side of blade;

and p.s. = pressure side of blade.

And where

$$\text{Life} = 0.75 \times t / \text{MDPR},$$

where t = blade thickness, mm;

MDPR = mean depth of penetration rate, mm/hour.

$$\text{MDPR} = \left[C \times (L_{\text{cav}}/10)^n \times (\tau_A - \phi_e^2)^3 \times U_e^6 \times \rho_L^3 \times A \right] / \left[8 \times F_{\text{mat}} \times (\text{TS})^2 \right] \text{ mm/h}$$

Where C = 8.28 E-06 (s.s.), 396 E-06 (p.s.); and n = 2.83 (s.s.), 2.6 (p.s.);

$\tau = \text{NPSH} / (U_e^2 / 2g)$; dimension less

U_e is blade inlet tip speed in m/s

$\phi_e = V_{m,1} / U_e$, where $V_{m,1}$ = average axial inlet velocity, (typically $\phi_e = 0.25$);

$\rho_L = 1000 \times \text{sp. gravity of the liquid}$; A = 1 for cold water, 0.705 for 350°F (177°C) water;

$F_{\text{mat}} = 1$ for martensitic: stainless steel, 1.7 for austenitic stainless steel;

TS = tensile strength in Pa [= 860,000,000 (= 125,000 psi) for 13 Cr and
= 552,000,000 (= 80,000 psi) for 18 Cr, 8 Ni.]

$$L_{\text{cav}} \approx (\pi \times D_e / n_b) \times \left\{ 1 - [(\tau_A - \tau_{3\%}) / (\tau_i - \tau_{3\%})]^{1/3} \right\} \text{ if } \tau_A < \tau_i \text{ (mm)}$$

$$L_{\text{cav}} = 0 \text{ if } \tau_A > \tau_i$$

Moreover, corrosion can play a role in cavitation-related erosive activity, an effect that was also addressed in Gülich's work.⁷⁸ Nevertheless, the ability to compute erosive behavior—even at the BEP—allows one to evaluate design improvements and provides a good idea of the life that can be expected under normal operating conditions.

Obviously, if the available *NPSH* is greater than the inception-*NPSH* (that is, $\tau_A > \tau_i$), there is no bubble activity of any kind, and at Q_{BEP} the cavity length $L_{\text{cav}} = 0$. An illustration of what can be achieved in this regard is presented in Figures 24 and 25 of Section 9.5, which are the “before” and “after” photographs of the model impeller blades for the first stage of a 24,000 hp (18 MW) pipeline pump. Quasi-three dimensional analysis of the blade pressure loading led to changes in shape that eliminated the cavities^{53,75}. This complete absence of cavitation is becoming the desired objective for the design and application of new and upgraded multistage high-energy pump suction stages. This approach eliminates both the erratic mechanical behavior that occurs in response to unsteady cavity patterns and the erosion due to bubble collapse; thereby substantially increasing the life and reliability of such machines⁸⁰.

TABLE 20 Life of high-energy pump suction stage

A) Pump data for computing life [at the B.E.P. of 20,000 gpm (1,262 m³/s)]

- $NPSH_{3\%} = 307 \text{ ft (94 m)}$; thus, $\tau_{3\%} = 0.263$
- $NPSHA = 519 \text{ ft (158 m)}$; thus, $\tau_A = 0.444$
- $t_{blade} = 0.42 \text{ in (10.7 m)}$; thus, $F_{mat} = 1$ (13 Cr martensitic stainless steel)
- Suction-side cavitation in 350°F (177°C) boiler feedwater, for which $A=0.705$
- Inlet flow coefficient $\phi_e=0.3$; $U_e = 274.2 \text{ ft/sec (83.57 m/s)}$; $U_e^2/2g=1168\text{ft (356 m)}$

B) Results for inception occurring at $NPSH_i = \text{blade inlet tip speed head and half that } NPSH_i$.

| | |
|--|--|
| a) $\tau_i=1.0 = 3.8 \times \tau_{3\%}$ | b) $\tau_i=0.5 = 1.9 \times \tau_{3\%}$ |
| $NPSH_i = 1168 \text{ ft (356 m)}$ | $NPSH_i = 584 \text{ ft (178 m)}$ |
| $L_{cav} = 57.0 \text{ mm}$ | 13.1 mm |
| $MDPR = 0.0014482 \text{ mm/hour}$ | $0.000022257 \text{ mm/hour}$ |
| $\text{Life} = 5,541 \text{ hours} = 7.6 \text{ months}$ | $360,000 \text{ hours} = 41 \text{ years}$ |

C) Sample Life Calculation $\left\{ \begin{array}{l} \text{High Energy} \\ \text{Pump Suction Stage} \end{array} \right.$

$$L_{cav} = 25.4 \times \frac{\pi \times 13.37}{7} \times \left[1 - \left(\frac{0.444 - 0.263}{1 - 0.263} \right)^{1/3} \right] = \underline{57.0 \text{ mm}}$$

$$MDPR = \frac{8.28 \times 10^{-6} \times \left(\frac{57}{10} \right)^{2.83} \times \left(0.444 - 0.3^2 \right) \times (83.57)^6 \times (890)^3 \times 0.705}{8 \times 1 \times \left(860 \times 10^6 \right)^2}$$

$$= 0.0014482 \text{ mm / hour} \left(\times 8760 \frac{\text{hr}}{\text{year}} = 12.7 \text{ mm/yr} \right)$$

$$\begin{aligned} \text{Life} &= 0.75 \times 10.7/0.0014482 &= \underline{5,541 \text{ hours}} \\ & &= \underline{7.6 \text{ months}} \end{aligned}$$

SECTION 2.2

CENTRIFUGAL PUMP CONSTRUCTION

2.2.1 CENTRIFUGAL PUMPS: MAJOR COMPONENTS

IGOR J. KARASSIK
C. C. HEALD

CLASSIFICATION AND NOMENCLATURE

A centrifugal pump consists of a set of rotating vanes enclosed within a housing or casing that is used to impart energy to a fluid through centrifugal force. Thus, stripped of all refinements, a centrifugal pump has two main parts: (1) a rotating element, including an impeller and a shaft, and (2) a stationary element made up of a casing, casing cover, and bearings.

In a centrifugal pump, the liquid is forced by atmospheric or other pressure into a set of rotating vanes. These vanes constitute an impeller that discharges the liquid at its periphery at a higher velocity. This velocity is converted to pressure energy by means of a volute (see Figure 1) or by a set of stationary diffusion vanes (see Figure 2) surrounding the impeller periphery. Pumps with volute casings are generally called *volute pumps*, while those with diffusion vanes are called *diffuser pumps*. Diffuser pumps were once quite commonly called *turbine pumps*, but this term has become more selectively applied to the vertical deep-well centrifugal diffuser pumps usually referred to as *vertical turbine pumps*. Figure 1 shows the path of the liquid passing through an end-suction volute pump operating at rated capacity (the capacity at which best efficiency is obtained).

Impellers are classified according to the major direction of flow in reference to the axis of rotation. Thus, centrifugal pumps may have the following:

- Radial-flow impellers (see Figures 25, 34, 35, 36, and 37)
- Axial-flow impellers (see Figure 29)
- Mixed-flow impellers, which combine radial- and axial-flow principles (see Figures 27 and 28)

FIGURE 1 A typical single-stage, end-suction volute pump (Flowserve Corporation)

FIGURE 2 A typical diffuser-type pump

Impellers are further classified in one of two categories:

- Single-suction, with a single inlet on one side (see Figures 25, 33, and 37)
- Double-suction, with liquid flowing to the impeller symmetrically from both sides (see Figures 26, 27, and 38)

The mechanical construction of the impellers gives a still further subdivision into

- Enclosed, with shrouds or side walls enclosing the waterways (see Figures 25, 26, and 27)
- Open, with no shrouds (see Figures 29, 33, and 34)
- Semiopen or semi-enclosed (see Figure 36)

A pump in which the head is developed by a single impeller is called a *single-stage pump*. Often the total head to be developed requires the use of two or more impellers operating in a series, each taking its suction from the discharge of the preceding impeller. For this purpose, two or more single-stage pumps can be connected in a series or all the impellers can be incorporated in a single casing. The unit is then called a *multistage pump*.

The mechanical design of the casing provides the added pump classification of *axially split* or *radially split*, and the axis of rotation determines whether the pump is a horizontal or vertical unit.

Horizontal-shaft centrifugal pumps are classified still further according to the location of the suction nozzle:

- End-suction (see Figures 1, 8, 11, and 13)
- Side-suction (see Figures 7 and 10)
- Bottom-suction (see Figure 15)
- Top-suction (see Figure 22)

Some pumps operate in air with the liquid coming to and being conducted away from the pumps by piping. Other pumps, most often vertical types, are submerged in their suction supply. Vertical-shaft pumps are therefore called either *dry-pit* or *wet-pit* types. If the wet-pit pumps are axial-flow, mixed-flow, or vertical-turbine types, the liquid is discharged up through the supporting drop or column pipe to a discharge point above or below the supporting floor. These pumps are consequently designated as *aboveground discharge* or *belowground discharge units*.

Figures 3, 4, and 8 show typical constructions of a horizontal double-suction volute pump, the bowl section of a single-stage axial-flow propeller pump, and a vertical dry-pit single-suction volute pump, respectively. The names recommended by the Hydraulic Institute for various pump parts are given in Table 1.

CASINGS AND DIFFUSERS

The Volute Casing Pump This pump (refer to Figure 1) derives its name from the spiral-shaped casing surrounding the impeller. This casing section collects the liquid discharged by the impeller and converts velocity energy to pressure energy.

A centrifugal pump volute increases in area from its initial point until it encompasses the full 360° around the impeller and then flares out to the final discharge opening. The

^aThese parts are called out in Figures 3, 4, and 8.

wall dividing the initial section and the discharge nozzle portion of the casing is called the tongue of the volute or the “cutwater.” The diffusion vanes and concentric casing of a diffuser pump fulfill the same function as the volute casing in energy conversion.

In propeller and other pumps in which axial-flow impellers are used, it is not practical to use a volute casing. Instead, the impeller is enclosed in a pipe-like casing. Generally, diffusion vanes are used following the impeller proper, but in certain extremely low-head units these vanes may be omitted.

A diffuser is seldom applied to a single-stage, radial-flow pump, except in special instances where volute passages become so small that machined or precision-cast volute or diffuser-like pieces are utilized for precise flow control. Conventional diffusers are often applied to multistage pump designs in conjunction with guide vanes to direct the flow efficiently from one impeller (stage) to another in a minimum radial and axial space. Diffuser vanes are used as the primary construction method for vertical turbine pumps and single-stage, low-head propeller pumps (see Figure 4).

Radial Thrust In a *single-volute pump casing* design (see Figure 5), uniform or near uniform pressures act on the impeller when the pump operates at design capacity (which coincides with the best efficiency). At other capacities, the pressures around the impeller are not uniform (see Figure 6) and there is a resultant radial reaction (F). A detailed discussion of the radial thrust and of its magnitude is presented in Subsection 2.3.1. Note that the unbalanced radial thrust increases as capacity decreases from that at the design flow.

For any percentage of capacity, this radial reaction is a function of total head and of the width and diameter of the impeller. Thus, a high-head pump with a large impeller diameter will have a much greater radial reaction force at partial capacities than a low-head

FIGURE 4 Vertical wet-pit diffuser pump bowl (the number refers to parts listed in Table 1) (Flowserve Corporation)

FIGURE 5 Uniform casing pressures exist at design capacity, resulting in zero radial reaction.

pump with a small impeller diameter. A zero radial reaction is not often realized; the minimum reaction occurs at design capacity.

Although the same tendency for unbalance exists in the diffuser-type pump, the reaction is limited to a small arc repeated all around the impeller. As a result, the individual reactions cancel each other out as long as flow is constantly removed from around the periphery of the diffuser discharge. If flow is not removed uniformly around its periphery, a pressure imbalance may occur around the diffuser discharge that will be transmitted back through the diffuser to the impeller, resulting in a radial reaction on the shaft and bearing system.

In a centrifugal pump design, shaft diameter as well as bearing size can be affected by the allowable deflection as determined by the shaft span, impeller weight, radial reaction forces, and torque to be transmitted.

Formerly, standard designs compensated for radial reaction forces encountered at capacities in excess of 50 percent of the design capacity for the maximum-diameter impeller of the pump. For sustained operations at lower capacities, the pump manufacturer, if properly advised, would supply a heavier shaft, usually at a much higher cost. Sustained operations at extremely low flows without the manufacturer being informed at the time of purchase are a much more common practice today. This can result in broken shafts, especially older designs, on high-head units.

Because of the increasing application of pumps that must operate at reduced capacities, it has become desirable to design standard units to accommodate such conditions. One solution is to use heavier shafts and bearings. Except for low-head pumps in which only a small additional load is involved, this solution is not economical. The only practical answer is a casing design that develops a much smaller radial reaction force at partial capacities. One of these is the *double-volute* casing design, also called the *twin-volute* or *dual-volute* design.

The application of the double-volute design principle to neutralize radial reaction forces at reduced capacity is illustrated in Figure 7. Basically, this design consists of two 180° volutes, and a passage external to the second joins the two into a common discharge. Although a pressure unbalance exists at partial capacity through each 180° arc, the two

FIGURE 6 At reduced capacities, uniform pressures do not exist in a single-volute casing, resulting in a radial reaction F .

FIGURE 7 Transverse view of a double-volute casing pump.

forces are approximately equal and opposite. Thus, little if any radial force acts on the shaft and bearings. Subsection 2.3.1 also covers this topic.

The double-volute design has many hidden advantages. For example, in large-capacity medium- and high-head single-stage vertical pumps, the rib forming the second volute that separates it from the discharge waterway of the first volute strengthens the casing (see Figure 8).

The individual stages of a multistage pump can be made double volute, as illustrated in Figure 9. The kinetic energy of the pumped liquid discharged from the impeller must be transformed into pressure energy and then must be turned 180° to enter the impeller of the next stage. The double volute therefore also acts as a return channel. The back view in Figure 9 shows this as well as the guide vanes used to straighten the flow into the next stage. An alternative to the volute design for multistage pumps is the diffuser and its return vanes that channel the flow from the discharge of the diffuser vanes back into the impeller of the next stage.

Solid and Split Casings *Solid casing* implies a design in which the discharge waterways leading to the discharge nozzle are all contained in one casting or fabricated piece. The casing must have one side open so that the impeller can be introduced into it. Because the sidewalls surrounding the impeller are actually part of the casing, a solid casing, strictly speaking, cannot be used, and designs normally called solid casing are really radially split (refer to Figure 1 and see Figures 11, 12, and 13).

A *split casing* is made of two or more parts fastened together. The term *horizontally split* had regularly been used to describe pumps with a casing divided by a horizontal plane through the shaft centerline or axis (see Figure 10). The term *axially split* is now preferred. Because both the suction and discharge nozzles are usually in the same half of the casing, the other half may be removed for inspection of the interior without disturbing the bearings or the piping. Like its counterpart horizontally split, the term *vertically split* is poor terminology. It refers to a casing split in a plane perpendicular to the axis of rotation. The term *radially split* is now preferred.

End-Suction Pumps Most end-suction, single-stage pumps are made of one-piece solid casings. At least one side of the casing must be open so that the impeller can be assembled in the pump. Thus, a cover is required for that side. If the cover is on the suction side, it becomes the casing sidewall and contains the suction opening (refer to Figure 1). This is called the *suction cover* or *casing suction head*. Other designs are made with casing covers (see Figure 12) and still others have both casing suction covers and casing covers (refer to Figure 8 and see Figure 13).

FIGURE 8 The sectional view of a vertical-shaft, end-suction pump with a double-volute casing (the numbers refer to parts listed in Table 1) (Flowserve Corporation)

FIGURE 9 The double volute of a multistage pump, front view (left) and back view (right) (Flowserve Corporation)

For general service, the end-suction, single-stage pump design is extensively used for small pumps with a 4- or 6-in (102 or 152 mm) discharge size for both motor-mounted and coupled types. In these pumps, the small size makes it feasible to cast the volute and one side integrally. Whether or not the seal chamber side or the suction side is made integrally with the casing is usually determined by the most economical pump design.

For larger pumps, especially those for special services such as sewage handling, there is a demand for pumps of both rotations. A design with separate suction and seal chamber heads permits the use of the same casing for either rotation if the flanges on the two sides

FIGURE 10 An axially split casing, horizontal-shaft, double-suction volute pump (Flowserve Corporation)

FIGURE 11 End-suction pump with semi-open impeller (Flowserve Corporation)

are made identical. There is also a demand for vertical pumps that can be disassembled by removing the rotor and bearing assembly from the top of the casing. Many horizontal applications of the pumps of the same line, however, require partial dismantling from the suction side. Such lines are most adaptable when they have separate suction and casing covers.

Casing Construction for Open- and Semiopen-Impeller Pumps In the open- or semiopen impeller pump, the impeller rotates within close clearance of the pump casing or suction cover (refer to Figure 11). If the intended service is abrasive, a side plate is mounted within the casing to provide a renewable close-clearance guide to the liquid flow-

FIGURE 12 End-suction pump with semi-open impeller, inducer and renewable side plate (Flowserve Corporation)

FIGURE 13 End-suction pump with removable suction and stuffing box heads (Flowserve Corporation)

ing through the impeller (refer to Figure 12). One of the advantages of using side plates is that abrasion-resistant material, such as stainless steel, can be used for the impeller and side plate, while the casing itself may be of a less costly material. Although double-suction, semiopen-impeller pumps are seldom used today, they were common in the past and were generally made with side plates.

In order to maintain pump efficiency, a close running clearance is required between the front unshrouded face of the open or semiopen impeller and the casing, suction cover, or side plate. Pump designs provide either jackscrews or shims to adjust the position of the thrust bearing housing (and, as a result, the axial position of the shaft and impeller) relative to the bearing frame.

Pre-rotation and Stop Pieces Improper entrance conditions and inadequate suction approach shapes may cause the liquid column in the suction pipe to spiral for some distance ahead of the impeller entrance. This phenomenon is called *pre-rotation*, and it is attributed to various operational and design factors in both vertical and horizontal pumps.

Pre-rotation is usually harmful to pump operation because the liquid enters between the impeller vanes at an angle other than that allowed in the design. This frequently lowers the net effective suction head and the pump efficiency. Various means are used to avoid pre-rotation both in the construction of the pump and in the design of the suction approaches.

FIGURE 14 Possible positions of discharge nozzles for a specific design of an end-suction, solid-casing, horizontal-shaft pump. The rotation illustrated is counterclockwise from suction end.

FIGURE 15 A bottom-suction, axially split casing single-stage pump (Flowsolve Corporation)

Practically all horizontal, single-stage, double-suction pumps and most multistage pumps have a suction volute that guides the liquid in a streamline flow to the impeller eye. The flow comes to the eye at right angles to the shaft and separates unequally on the two sides of the shaft. Moving from the suction nozzle to the impeller eye, the suction waterways are reduced in area, meeting in a projecting section of the sidewall dividing the two sections. This dividing projection is called a *stop piece*. To minimize pre-rotation in end-suction pumps, a radial-fin stop piece projecting toward the center is sometimes cast into the suction nozzle wall.

Nozzle Locations The discharge nozzle of end-suction, single-stage horizontal pumps is usually in a top-vertical position (refer to Figures 1, 11, and 12). However, other nozzle positions can be obtained, such as top-horizontal, bottom-horizontal, or bottom-vertical. Figure 14 illustrates the flexibility available in discharge nozzle locations. Sometimes the pump frame, bearing bracket, or baseplate may interfere with the discharge flange, prohibiting a bottom-horizontal or bottom-vertical discharge nozzle position. In other instances, solid casings cannot be rotated for various nozzle positions because the seal chamber connection would become inaccessible.

Practically all double-suction, axially split casing pumps have a side discharge nozzle and either a side- or a bottom-suction nozzle. If the suction nozzle is placed on the side of the pump casing with its axial centerline (refer to Figure 10), the pump is classified as a *side-suction pump*. If its suction nozzle points vertically downward (see Figure 15), the pump is called a *bottom-suction pump*. Single-stage, bottom-suction pumps are rarely made in sizes below a 10-in (254 mm) discharge nozzle diameter.

Special nozzle positions can sometimes be provided for double-suction, axially split casing pumps to meet special piping arrangements, such as a radically split casing with bottom suction and top discharge in the same half of the casing. Such special designs are generally costly and should be avoided.

Centrifugal Pump Rotation Because suction and discharge nozzle locations are affected by pump rotation, it is important to understand how the direction of rotation is defined. According to Hydraulic Institute standards, rotation is defined as clockwise or counterclockwise by looking at the driven end of a horizontal pump or looking down on a vertical pump. To avoid misunderstanding, clockwise or counterclockwise rotation should always be qualified by including the direction from which one looks at the pump.

The terms *inboard end* or *drive end* (the end of the pump closest to the driver) and *outboard end* or *nondrive end* (the end of the pump farthest from the driver) are used only with horizontal pumps. The terms lose their significance with dual-driven pumps. Any centrifugal pump casing pattern can be arranged for either clockwise or counterclockwise rotation, except for end-suction pumps, which have integral heads on one side. These require separate directional patterns.

Casing Handholes Casing handholes are furnished primarily on pumps handling sewage and stringy materials that may become lodged on the impeller suction vane edges or on the tongue of the volute. The holes permit removal of this material without completely dismantling the pump. End-suction pumps used primarily for liquids of this type are provided with handholes or access to the suction side of the impellers. These access points are located on the suction head or in the suction elbow. Handholes are also provided in drainage, irrigation, circulating, and supply pumps if foreign matter may become lodged in the waterways. On very large pumps, manholes provide access to the interior for both cleaning and inspection.

Mechanical Features of Casings Most single-stage centrifugal pumps are intended for service at moderate pressures and temperatures. As a result, pump manufacturers usually design a special line of pumps for high operating pressures and temperatures rather than make their standard line unduly expensive by making it suitable for too wide a range of operating conditions.

If axially split casings are subject to high pressure, they tend to “breathe” at the split joint, leading to misalignment of the rotor and, even worse, leakage. For such conditions, internal and external ribbing is applied to casings at the points subject to the greatest stress. In addition, whereas most pumps are supported by feet at the bottom of the casing, high temperatures require centerline support so that, as the pump becomes heated, expansion will not cause misalignment.

Series Units For large-capacity medium-high-head conditions, two single-stage, double-suction pumps can be connected in a series on one baseplate with a single driver. Such an arrangement was at one time very common in waterworks applications for heads of 250 to 400 ft (76 to 122 m). One series arrangement uses a double-extended shaft motor in the middle, driving two pumps connected in a series by external piping. In a second type, a standard motor is used with one pump having a double-extended shaft. This latter arrangement may have limited applications because the shaft of the pump next to the motor must be strong enough to transmit the total pumping horsepower. If the total pressure generated by such a series unit is relatively high, the casing of the second pump could require ribbing. Higher heads per stage are becoming more and more common, and series units are generally used in only very high ranges of total head.

MULTISTAGE PUMP CASINGS

Although the majority of single-stage pumps are of the volute-casing type, both volute and diffuser casings are used in multistage pump construction. Because a volute casing gives rise to radial thrust, axially split multistage casings generally have staggered volutes so that the resultant of the individual radial thrusts is balanced out (see Figures 16 and 17). Both axially and radially split casings are used for multistage pumps. The choice between the two designs is dictated by the design pressure, with 2000 lb/in² (138 bar)^o being typical for 3600-rpm axially split casing pumps.

^o1 bar = 10⁵ Pa

FIGURE 16 An arrangement of a multistage volute pump for radial-thrust balance

FIGURE 17 The horizontal flange of an axially split casing, six-stage pump (Flowserve Corporation)

Axially Split Casings Regardless of the arrangement of the stages in the casing, it is necessary to connect the successive stages of a multistage pump. In the low and medium pressure and capacity ranges, these interstage passages are cast integrally with the casing proper (see Figures 18 and 19). As the pressures and capacities increase, the desire to maintain as small a casing diameter as possible, coupled with the necessity of avoiding sudden changes in the velocity or the direction of the flow, leads to the use of external interstage passages cast separately from the pump casing. They are formed in the shape of a loop, bolted or welded to the casing proper (see Figure 20).

Interstage Construction for Axially Split Casing Pumps A multistage pump inherently has adjoining chambers subjected to different pressures, and means must be made available to isolate these chambers from one another so that the leakage from high to low pressure will take place only at the clearance joints formed between the stationary and rotating elements of the pump. Thus, the leakage will be kept to a minimum. The isolating wall used to separate two adjacent chambers of a multistage pump is called a *stage piece*, *diaphragm*, or *inter-stage diaphragm*. The stage piece may be formed of a single piece, or it may be fitted with a renewable stage piece bushing at the clearance joint between the stationary stage piece and the part of the rotor immediately inside the former. The stage pieces, which are usually solid, are assembled on the rotor along with impellers, sleeves, bearings,

FIGURE 18 Two-stage axially split casing volute pump for small capacities and pressures up to 450 lb/in² (31 bar) (Flowserve Corporation)

FIGURE 19 Two-stage axially split casing volute pump for pressures up to 500 lb/in² (34 bar) (Flowserve Corporation)

FIGURE 20 A six-stage, axially split casing volute pump for pressures up to 1,300 lb/in² (90 bar) (Flowserve Corporation)

and similar components. To prevent the stage pieces from rotating, a locked tongue-and-groove joint is provided in the lower half of the casing. Clamping the upper casing half to the lower half securely holds the stage piece and prevents rotation.

The problem of seating a solid stage piece against an axially split casing is one that has given designers much trouble. First, there is a three-way joint and, second, this seating must make the joint tight and leakproof under a pressure differential without resorting to bolting the stage piece directly to the casing.

To overcome this problem, it is wise to make a pump that has a small-diameter casing so that when the casing bolting is pulled tight, there is a seal fitting of the two casing halves adjacent to the stage piece. The small diameter likewise helps to eliminate the possibility of a stage piece cocking and thereby leaving a clearance on the upper-half casing when it is pulled down. No matter how rigidly the stage piece is located in the lower-half casing, there must be a sliding fit between the seat face of the stage piece and that in the upper-half casing so that the upper-half casing can be pulled down. Each stage piece, furthermore, must be arranged so that the pressure differential developed by the pump will tend to seat the piece tightly against the casing rather than open up the joint.

We have said that axially split casing pumps are typically used for working pressures of up to 2,000 lb/in² (138 bar). High-pressure piping systems, of which these pumps form a part, are inevitably made of steel because this material has the valuable property of yielding without breaking. Considerable piping strains are unavoidable, and these strains, or at least a part thereof, are transmitted to the pump casing. The latter consists essentially of a barrel that is split axially, flanged at the split, and fitted with two necks that serve as inlet and discharge openings. When piping stresses exist, these necks, being the weakest part of the casing, are in danger of breaking off if they cannot yield. Steel is therefore the safest material for pump casings whenever the working pressures in the pump are in excess of 1,000 lb/in² (70 bar).

This brings up an important feature in the design of the suction and discharge flanges. Although raised-face flanges are perfectly satisfactory for steel-casing pumps, their use is extremely dangerous with cast-iron pumps. This danger arises from the lack of elasticity in cast iron, which leads to flange breakage when the bolts are being tightened, the fulcrum of the bending moment being located inward from the bolt circle. As a result, it is essential to avoid raised-face flanges with cast-iron casings as well as the use of a raised-face flange pipe directly against a flat-face cast-iron pump flange. Suction flanges should obviously be suitable for whatever hydrostatic test pressure is applied to the pump casing.

The location of the pump casing feet is not critical in smaller pumps operating at discharge pressures below 275 lb/in² (19 bar) and at moderate temperatures of up to 300°F (150°C). Since the unit is relatively small, very little distortion is likely to occur. However, for larger units operating at higher pressures and temperatures, it is important that the casing be supported at the horizontal centerline or immediately below the bearings (refer to Figures 19 and 20).

Radially Split Double-Casing Pumps The oldest form of radially split casing multistage pump is commonly called the *ring-section*, *ring-casing*, or the *doughnut type*. When more than one stage was found necessary to generate higher pressures, two or more single-stage units of the prevalent radially split casing type were assembled and bolted together.

In later designs, the individual stage sections and separate suction and discharge heads were held together with large throughbolts. These pumps, still an assembly of bolted-up sections, can present serious dismantling and reassembly problems because suction and discharge connections have to be broken each time the pump is serviced. The double-casing pump retains the advantages of the radially split casing design and minimizes the dismantling problem.

The basic principle consists of enclosing the working parts of a multistage centrifugal pump in an inner casing and building a second casing around this inner casing. The space between the two casings is maintained at the discharge pressure of the last pump stage. The construction of the inner casing follows one of two basic principles: (1) axial splitting (see Figure 21) or (2) radial splitting (see Figure 22).

FIGURE 21 Double-casing multistage pump with axially split inner casing (Allis-Chalmers)

FIGURE 22 Double-casing multistage pump with radially split inner casing (Flowserve Corporation)

The double-casing pump with radially split inner casing is an evolution of the ring-casing pump with added provisions to ease dismantling. The inner unit is generally constructed exactly as a ring-casing pump. After assembly, it is inserted and bolted inside a cylindrical casing that supports it and leaves it free to expand under temperature changes. In Figure 23, the inner assembly of such a pump is being inserted into the outer casing. Figure 24 shows the external appearance of this type of pump. The suction and discharge nozzles form an integral part of the outer casing, and the internal assembly of the pump can be withdrawn without disturbing the piping connections.

Hydrostatic Pressure Tests It is standard practice for the manufacturer to conduct hydrostatic tests for the parts of a pump that contain fluid under pressure. This means that the pump casing and, where applicable, parts like suction or casing covers are assembled with the internal parts, removed, and are then subjected to a hydrostatic test, generally for a minimum of 30 minutes. Such a test demonstrates that the casing containment is sound and that there is no leakage of fluid to the exterior.

Additional tests may be conducted by the pump manufacturer to determine the soundness of internal partitions separating areas of the pump operating under different pressures.

FIGURE 23 Rotor assembly of a radially split, double-casing pump being inserted into its outer casing (Flowserve Corporation)

FIGURE 24 Multistage radially split, double-casing pump (Flowserve Corporation)

The definition of the applicable hydrostatic pressure for these tests varies. The most generally accepted definition is that given by the Hydraulic Institute Standards. Each part of the pump that contains fluid under pressure shall be capable of withstanding a hydrostatic test at not less than the greatest of the following:

- 150 percent of the pressure that will occur in that part when the pump is operated at rated conditions for the given application of the pump, except thermoset parts
- 125 percent of the pressure that would occur in that part when the pump is operating at rated speed for a given application, but with the pump discharge valve closed

IMPELLERS

In a single-suction impeller, the liquid enters the suction eye on one side only. A double-suction impeller is, in effect, two single-suction impellers arranged back to back in a single casing. The liquid enters the impeller simultaneously from both sides, while the two casing suction passageways are connected to a common suction passage and a single suction nozzle.

For the general service single-stage, axially split casing design, a double-suction impeller is favored because it is theoretically in an axial hydraulic balance and because the greater suction area of a double-suction impeller permits the pump to operate with less net absolute suction head. For small units, the single-suction impeller is more practical for manufacturing reasons, as the waterways are not divided into two very narrow passages. It is also sometimes preferred for structural reasons. End-suction pumps with single-suction overhung impellers have both first-cost and maintenance advantages unobtainable with double-suction impellers. Most radially split casing pumps therefore use single-suction impellers. Because an overhung impeller does not require the extension of a shaft into the impeller suction eye, single-suction impellers are preferred for pumps handling suspended matter, such as sewage. In multistage pumps, single-suction impellers are almost universally used because of the design and first-cost complexity that double-suction staging introduces.

Impellers are called radial vane or radial flow when the liquid pumped is made to discharge radially to the periphery. Impellers of this type usually have a specific speed below 4200 (2600) if single-suction and below 6000 (3700) if double-suction. Specific speed is discussed in detail in Subsection 2.3.1. The units for specific speed used here are in USCS rpm, gallons per minute, and feet. In SI, they are rpm, liters per second, and meters. Impellers can also be classified by the shape and form of their vanes:

- The straight-vane impeller (see Figures 25, 34, 35, 36, and 37)
- The Francis-vane or screw-vane impeller (see Figures 26 and 27)
- The mixed-flow impeller (see Figure 28)
- The propeller or axial-flow impeller (see Figure 29)

In a *straight-vane radial impeller*, the vane surfaces are generated by straight lines parallel to the axis of rotation. These are also called *single-curvature vanes*. The vane surfaces of a *Francis-vane radial impeller* have a double curvature. An impeller design that has both a radial-flow and an axial-flow component is called a *mixed-flow impeller*. It is generally restricted to single-suction designs with a specific speed above 4200 (2600). Types with lower specific speeds are called *Francis-vane impellers*. Mixed-flow impellers with a small radial-flow component are usually referred to as propellers. In a true propeller, or *axial-flow impeller*, the flow strictly parallels the axis of rotation. In other words, it moves only axially.

An inducer is a low-head, axial-flow impeller with few blades that is placed in front of a conventional impeller. The hydraulic characteristics of an inducer are such that it requires considerably less NPSH than a conventional impeller. Both inducer and impeller

FIGURE 25 Straight-vane, radial, single-suction closed impeller (Flowserve Corporation)

FIGURE 26 Francis-vane, radial, double-suction closed impeller (Flowserve Corporation)

FIGURE 27 High-specific-speed, Francis-vane, radial, double-suction closed impeller (Flowserve Corporation)

FIGURE 28 Open mixed-flow impeller (Flowserve Corporation)

FIGURE 29 Axial-flow impeller (Flowserve Corporation)

are mounted on the same shaft and rotate at the same speed (see Figure 30). The main purpose of the inducer is not to generate an appreciable portion of the total pump head, but to increase the suction pressure to a conventional impeller. Inducers are therefore used to reduce the NPSH requirements of a given pump or to permit the pump to operate at higher speeds with a given available NPSH. For a further discussion of inducers, see Section 2.1 and Subsection 2.3.1.

The relation of single-suction impeller profiles to specific speed is shown in Figure 31. The classification of impellers according to their vane shape is naturally arbitrary inasmuch as there is much overlapping in the types of impellers used in the different types of pumps. For example, impellers in single- and double-suction pumps of low specific speeds have vanes extending across the suction eye. This provides a mixed flow at the impeller entrance for low pickup losses at high rotative speeds but enables the discharge portion of the impeller to use the straight-vane principle. In pumps of higher specific speed operating against low heads, impellers have double-curvature vanes extending over the full vane surface. They are therefore full Francis-type impellers. The mixed-flow impeller, usually a single-suction type, is essentially one-half of a double-suction, high-specific-speed, Francis-vane impeller.

In addition, many impellers are designed for specific applications. For instance, the conventional impeller design with sharp vane edges and restricted areas is not suitable for handling liquids containing rags, stringy materials, and solids like sewage because it will become clogged. Special nonclogging impellers with blunt edges and large waterways have been developed for such services (see Figure 32). For pumps up to the 12- to 16-in (305- to 406-mm) discharge size, these impellers have only two vanes. Larger pumps normally use three or four vanes.

FIGURE 30 A centrifugal pump with a conventional impeller preceded by an inducer (Flowserve Corporation)

Another impeller design used for paper pulp pumps (see Figure 33) is fully open and nonclogging; it has screw and radial streamlined vanes. The screw-conveyor end projects far into the suction nozzle, permitting the pump to handle high-consistency paper pulp stock.

Impeller Mechanical Types Mechanical design also determines impeller classification. Accordingly, impellers may be completely open, semiopen, or closed.

Strictly speaking, an *open impeller* (see Figures 34 and 35) consists of nothing but vanes attached to a central hub for mounting on the shaft without any form of sidewall or shroud. The disadvantage of this impeller is structural weakness. If the vanes are long, they must be strengthened by ribs or a partial shroud. Generally, open impellers are used in small, low energy pumps. One advantage of open impellers is that they are better suited for handling liquids containing stringy materials. It is also sometimes claimed that they are better suited for handling liquids containing suspended matter because the solids in such matter are more likely to be clogged in the space between the rotating shrouds of a closed impeller and the stationary casing walls. It has been demonstrated, however, that closed impellers do not clog easily, thus disproving the claim for the superiority of the open-impeller design. In addition, the open impeller is much more sensitive to wear than the closed impeller and therefore its efficiency may deteriorate rather rapidly.

The open impeller rotates between two side plates, between the casing walls of the volute, or between the casing cover and the suction head. The clearance between the impeller vanes and the sidewalls enables a certain amount of water slippage. This slippage increases as wear increases. To restore the original efficiency, both the impeller and the side plate(s) must be replaced. This, incidentally, involves a much larger expense than would be entailed in closed impeller pumps where simple rings form the leakage joint.

The *semiopen impeller* (see Figure 36) incorporates a single shroud, usually at the back of the impeller. This shroud may or may not have *pump-out vanes*, which are vanes located at the back of the impeller shroud (see Figure 37). This function reduces the pressure at the back hub of the impeller and prevents foreign matter from lodging in back of the impeller that would interfere with the proper operation of the pump and the seal chamber.

The *closed impeller* (refer to Figures 25 through 27), which is almost universally used in centrifugal pumps handling clear liquids, incorporates shrouds or sidewalls that totally enclose the impeller waterways from the suction eye to the periphery. Although this design prevents the liquid slippage that occurs between an open or semiopen impeller and its side plates, a running joint must be provided between the impeller and the casing to separate the discharge and suction chambers of the pump. This running joint is usually formed by a relatively short cylindrical surface on the impeller shroud that rotates within a slightly larger stationary cylindrical surface. If one or both surfaces are made renewable, the leakage joint can be repaired when wear causes excessive leakage.

FIGURE 31 Variations in impeller profiles with specific speeds and approximate ranges of specific speeds for the various types. [Universal specific speed $\Omega_u = N_g/2733$. N_g (in rpm, m^3/s , m) = $N_g/51.65$].

FIGURE 38 Parts of a double-suction impeller

If the pump shaft terminates at the impeller so that the latter is supported by bearings on one side, the impeller is called an *overhung impeller*. This type of construction is the best for end-suction pumps with single-suction impellers.

Impeller Nomenclature The inlet of an impeller just before the section where the vanes begin is called the suction eye (see Figure 38). In a closed-impeller pump, the suction eye diameter is taken as the smallest inside diameter of the shroud. In determining the area of the suction eye, the area occupied by the impeller shaft hub is deducted.

The *hub* is the central part of the impeller that is bored out to receive the pump shaft. The term, however, is also frequently used for the part of the impeller that rotates in the casing fit or in the casing wearing ring. It is then referred to as the *outer impeller hub* or the *wearing-ring hub* of the shroud.

WEARING RINGS

Wearing rings provide an easily and economically renewable leakage joint between the impeller and the casing. A leakage joint without renewable parts is illustrated in Figure 39. To restore the original clearances of such a joint after wear occurs, the user must either (1) build up the worn surfaces by welding or metal spraying, or (2) buy new parts.

The new parts are not very costly in small pumps, especially if the stationary casing element is a simple suction cover. This is not true for larger pumps or where the stationary element of the leakage joint is part of a complicated casting. If the first cost of a pump is of prime importance, it is more economical to provide for remachining both the stationary parts and the impeller. Renewable casing and impeller rings can then be installed (see Figures 40, 41, and 42). The nomenclature for the casing or stationary part forming the leakage joint surface is as follows: (1) *casing ring* (if mounted in the casing), (2) *casing ring* or *suction head ring* (if mounted in a suction cover or head), and (3) *casing cover ring* or *head ring* (if mounted in the casing cover or head). Some engineers like to identify the part

FIGURE 39 A plain flat leakage joint with no rings

FIGURE 40 A single flat casing ring construction.

further by adding the word *wearing*, such as *casing wearing ring*. A renewable part for the impeller wearing surface is called the *impeller ring*. Pumps with both stationary and rotating rings are said to have *double-ring construction*.

Wearing Ring Types Various types of wearing ring designs, and the selection of the most desirable type depends on the liquid being handled, the pressure differential across the leakage joint, the rubbing speed, and the particular pump design. In general, centrifugal pump designers use the ring construction that they have found to be most suitable for each particular pump service.

The most common ring constructions are the flat type (see Figures 40 and 41) and the L type. The leakage joint in the former is a straight, annular clearance. In the L-type ring (see Figure 43), the axial clearance between the impeller and the casing ring is large, so the velocity of the liquid flowing into the stream entering the suction eye of the impeller is low. The L-type casing rings shown in Figures 43 and 44 have the additional function of guiding the liquid into the impeller eye; they are called *nozzle rings*. Impeller rings of the L type shown in Figure 44 also furnish protection for the face of the impeller wearing ring hub.

Some designers favor labyrinth-type rings (see Figures 45 and 46) that have two or more annular leakage joints connected by relief chambers. In leakage joints involving a single unbroken path, the flow is a function of both the area and the length of the joint as well as of the pressure differential across the joint. If the path is broken by relief chambers (see to Figure 42, 45, and 46), the velocity energy in the jet is dissipated in each relief chamber, increasing the resistance. As a result, with several relief chambers and several leakage joints for the same actual flow through the joint, the area and hence the clearance between the rings can be greater than for an unbroken, shorter leakage joint.

The single labyrinth ring with only one relief chamber (refer to Figure 45) is often called an *intermeshing ring*. The *step-ring type* (refer to Figure 42) utilizes two flat-ring elements of slightly different diameters over the total leakage joint width with a relief chamber between the two elements. Other ring designs also use some form of relief chamber. For example, one commonly used in small pumps has a flat joint similar to that in Figure 40, but with one surface broken by a number of grooves. These act as relief chambers to dissipate the jet velocity head, thereby increasing the resistance through the joint and decreasing the leakage.

For raw water pumps in waterworks service and for larger pumps in sewage services in which the liquid contains sand and grit, *water-flushed rings* have been used (see Figure 47). Clear water under a pressure greater than that on the discharge side of the rings is piped to the inlet and distributed by the cored passage, the holes through the stationary ring, and the groove to the leakage joint. Ideally, the clear water should fill the leakage joint with some flow to the suction and discharge sides to prevent any sand or grit from getting into the clearance space. Wearing-ring flush is also employed in some process pumps when pumping solids or abrasives to minimize ring wear by injecting a compatible clean liquid between the rings.

FIGURE 41 A double flat ring construction

FIGURE 42 A step-type leakage joint with double rings

FIGURE 43 An L-type nozzle casing ring

FIGURE 44 Double rings, both of L type

In large pumps (with roughly a 36-in [900-mm] or larger discharge size), particularly vertical, end-suction, single-stage volute pumps, size alone permits some refinements not found in smaller pumps. One example is the inclusion of inspection ports for measuring ring clearance (see Figure 48). These ports can be used to check the impeller centering after the original installation as well as to observe ring wear without dismantling the pump.

The lower rings of large vertical pumps handling liquids containing sand and grit in intermittent services are highly susceptible to wear. During shutdown periods, the grit and sand settle out and naturally accumulate in the region where these rings are installed, as it is the lowest point on the discharge side of the pump. When the pump is started again, this foreign matter is washed into the joint all at once and causes wear. To prevent this action in medium and large pumps, a dam-type ring is often used (see Figure 49). Periodically, the pocket on the discharge side of the dam can be flushed out.

One problem with the simple water-flushed ring is the failure to get uniform pressure in the stationary ring groove. If pump size and design permit, two sets of wearing rings arranged in tandem and separated by a large water space (see Figure 50) provide the best solution. The large water space enables a uniform distribution of the flushing water to the full 360° degrees of each leakage joint. Because ring 2 is shorter and because a greater clearance is used there than at ring 1, equal flow can take place to the discharge pressure side and to the suction pressure side. This design also makes it easier to harden or coat the surfaces.

For pumps handling gritty or sandy water, the ring construction should provide an apron on which the stream leaving the leakage joint can impinge, as sand or grit in the jet will erode any surface it hits. Thus, a form of L-type casing ring similar to that shown in Figure 49 should be used.

FIGURE 45 A single-labyrinth, intermeshing type. It is a double-ring construction with a nozzle-type casing ring.

FIGURE 46 Labyrinth-type rings in a double-ring construction

FIGURE 47 Water-flushed wearing ring

FIGURE 48 Wearing ring with an inspection port for checking clearance

FIGURE 49 Dam-type ring construction

Wearing-Ring Location In some designs, leakage is controlled by an axial clearance (see Figure 51). Generally, this design requires a means of adjusting the shaft position for proper clearance. Then, if uniform wear occurs over the two surfaces, the original clearance can be restored by adjusting the position of the impeller. A limit exists to the amount of wear that can be compensated, because the impeller must be nearly central in the casing waterways.

FIGURE 50 Two sets of rings with space between for flushing water (Flowservice Corporation)

FIGURE 51 A leakage joint with axial clearance

Leakage joints with axial clearance are not popular for double-suction pumps because a very close tolerance is required in machining the fit of the rings in reference to the centerline of the volute waterways. Joints with radial clearances, however, enable some shifting of the impeller for centering. The only adverse effect is a slight inequality in the lengths of the leakage paths on the two sides.

So far, this discussion has treated only those leakage joints located adjacent to the impeller eye or at the smallest outside shroud diameter. Designs have been made where the leakage joint is at the periphery of the impeller. In a vertical pump, this design is advantageous because the space between the joint and the suction waterways is open and so sand or grit cannot collect. Because of rubbing speed and because the impeller diameters used in the same casing vary over a wide range, the design is impractical in regular pump lines.

Mounting Stationary Wearing Rings In small single-suction pumps with suction heads, a stationary wearing ring is usually pressed into a bore in the head and may or may not be further locked by several set screws located half in the head and half in the ring (refer to Figure 41). Larger pumps often use an L-type ring with the flange held against a face on the head. In axially split casing pumps, the cylindrical casing bore (in which the casing ring will be mounted) should be slightly larger than the outside diameter of the ring. Unless some clearance is provided, distortion of the ring may occur when the two casing halves are assembled. However, the joint between the casing ring and the

casing must be tight enough to prevent leakage. This is usually provided by a radial metal-to-metal joint (refer to Figure 43) arranged so that the discharge pressure presses the ring against the casing surface.

As it is not desirable for the casing ring of an axially split casing pump to be pinched by the casing, the ring will not be held tightly enough to prevent its rotation unless special provisions are made to keep it in place. One means of accomplishing this is to place a pin in the casing that will project into a hole bored in the ring or, conversely, to provide a pin in the ring that will fit into a hole bored in the casing or into a recess at the casing split joint.

Another method is to have a tongue on the casing ring that extends around 180° and engages a corresponding groove in one-half of the casing. This method can be used with casing rings having a central flange by making the diameter of the flange larger for 180° and cutting a deeper groove in that half of the casing.

Many methods are used for holding impeller rings on the impeller. Probably the simplest is to rely on a press fit of the ring on the impeller or, if the ring is of proper material, on a shrink fit. Designers do not usually feel that a press fit is sufficient and often add several machine screws or set screws located half in the ring and half in the impeller, as in Figure 41.

An alternative to axial machine screws being located half in the ring and half in the impeller is the radial pin, which goes through the center of the ring into the impeller (or from the inside of the impeller eye outward into the ring). This pinning method avoids having to drill and tap holes half in a hardened wearing ring and half in a softer impeller hub. For higher speeds, installing the radial pins from the inside of the impeller eye outward into the wearing ring captures the pins and protects against pin loss, especially at higher operating speeds. Generally, some additional locking method is used rather than relying solely on friction between the ring and the impeller.

In the design of impeller rings, consideration has to be given to the stretch of the ring caused by centrifugal force, especially if the pump is of a high-speed design for the capacity involved. For example, some pumps operate at speeds that would cause the rings to become loose if only a press fit is used. For such pumps, shrink fits should be used or, preferably, impeller rings should be eliminated.

Wearing-Ring Clearances Typical clearance and tolerance standards for nongalling wearing-joint metals in general service pumps are shown in Figure 52. They apply to the

FIGURE 52 Wearing-ring clearances for single-stage pumps using nongalling materials

following combinations: (1) bronze with a dissimilar bronze, (2) cast-iron with bronze, (3) steel with bronze, (4) Monel metal with bronze, and (5) cast-iron with cast iron. If the metals gall easily (like the chrome steels), the values given should be increased by 0.002 to 0.004 in.

The tolerance indicated is positive for the casing ring and negative for the impeller hub or impeller ring.

In a single-stage pump with a joint of nongalling components, the correct machining dimension for a casing-ring diameter of 9.000 in would be 9.000 plus 0.003 and minus 0.000 in. For the impeller hub or ring, the values would be 9.000 minus 0.018 (or 8.982) plus 0.000 and minus 0.003 in. Diametral clearances would be between 0.018 and 0.024 in. Obviously, clearances and tolerances are not translated into SI units by merely using conversion multipliers; they are rounded off as they are in the USCS system. The SI values for the previous USCS examples given are outlined here.

For a single-stage pump with a casing ring diameter of 230 millimeters, the machining dimensions would be as follows:

| | |
|----------------------|--|
| Casing ring | 230 plus 0.08 and minus 0.00 mm |
| Impeller hub | 230 minus 0.50 (229.5) plus 0.00 and minus 0.08 mm |
| Diametral clearances | Between 0.50 and 0.66 mm |

Naturally, the manufacturer's recommendation for ring clearances and tolerances should be followed.

AXIAL THRUST

Axial Thrust in Single-Stage Pumps with Closed Impellers The pressures generated by a centrifugal pump exert forces on both stationary and rotating parts. The design of these parts balances some of these forces, but separate means may be required to counterbalance others.

An axial hydraulic thrust on an impeller is the sum of the unbalanced forces acting in the axial direction. Because reliable, large-capacity thrust bearings are readily available, an axial thrust in single-stage pumps remains a problem only in larger, higher speed units. Theoretically, a double-suction impeller is in hydraulic axial balance, with the pressures on one side equal to and counterbalancing the pressures on the other (see Figure 53). In practice, this balance may not be achieved for the following reasons:

1. The suction passages to the two suction eyes may not provide equal or uniform flows to the two sides.
2. External conditions, such as an elbow located too close to the pump suction nozzle, may cause unequal flow to the two suction eyes.

FIGURE 53 The origin of pressures acting on impeller shrouds to produce an axial thrust

3. The two sides of the discharge casing waterways may not be symmetrical, or the impeller may be located off-center. These conditions will alter the flow characteristics between the impeller shrouds and the casing, causing unequal pressures on the shrouds.
4. Unequal leakage through the two leakage joints can upset the balance.

Combined, these factors can create an axial unbalance. To compensate for this, all centrifugal pumps, even those with double-suction impellers, incorporate thrust bearings.

The ordinary single-suction, closed, radial-flow impeller with the shaft passing through the impeller eye (refer to Figure 53) is subject to an axial thrust because a portion of the front wall is exposed to suction pressure and thus relatively more backwall surface is exposed to discharge pressure. If the discharge chamber pressure is uniform over the entire impeller surface, the axial force acting toward the suction would be equal to the product of the net pressure generated by the impeller and the unbalanced annular area.

Actually, pressure on the two single-suction, closed impeller walls is not uniform. The liquid trapped between the impeller shrouds and casing walls is in rotation, and the pressure at the impeller periphery is appreciably higher than the impeller hub. Although we need not be concerned with the theoretical calculations for this pressure variation, Figure 54 describes it qualitatively. Generally speaking, the axial thrust toward the impeller suction may be about 20 to 30 percent less than the product of the net pressure and the unbalanced area.

To eliminate the axial thrust of a single-suction impeller, a pump can be provided with both front and back wearing rings. To equalize the thrust areas, the inner diameter of both rings is made the same (see Figure 55). Pressure approximately equal to the suction pressure is maintained in a chamber located on the impeller side of the back wearing ring by

FIGURE 54 Pressure distribution on the front and back shrouds of the single-suction impeller with a shaft through the impeller eye

FIGURE 55 Balancing the axial thrust of a single-suction impeller by means of wearing rings on the back side and balancing holes

FIGURE 56 Pump-out vanes used in a single-suction impeller to reduce axial thrust

FIGURE 57 An axial thrust problem with a single-suction, overhung impeller and a single stuffing box or seal chamber

drilling balancing holes through the impeller. Leakage past the back wearing ring is returned to the suction area through these holes. However, with large single-stage, single-suction pumps, balancing holes are considered undesirable because leakage back to the impeller suction opposes the main flow, creating disturbances. In such pumps, a piped connection to the pump suction replaces the balancing holes.

Another way to eliminate or reduce an axial thrust in single-suction impellers is to use pump-out vanes on the back shroud. The effect of these vanes is to reduce the pressure acting on the back shroud of the impeller (see Figure 56). This design, however, is generally used only in pumps handling dirty liquids where it keeps the clearance space between the impeller back shroud and the casing free of foreign matter.

So far, our discussion of axial thrust has been limited to single-suction, closed impellers with a shaft passing through the impeller eye that are located in pumps with two seal chambers, one on either side of the impeller. In these pumps, suction-pressure magnitude does not affect the resulting axial thrust.

On the other hand, axial forces acting on an overhung impeller with a single seal chamber (see Figure 57) are definitely affected by suction pressure. In addition to the unbalanced force found in a single-suction, two-seal chamber design (refer to Figure 54), there is an axial force equivalent to the product of the shaft area through the seal chamber and the difference between suction and atmospheric pressure. This force acts toward the impeller suction when the suction pressure is less than atmospheric or in the opposite direction when it is higher than atmospheric.

When an overhung impeller pump handles a suction lift, the additional axial force is very low. For example, if the shaft diameter through the stuffing box is 2 in (50.8 mm)

(area = 3.14 in^2 or 20.26 cm^2), and if the suction lift is 20 ft (6.1 m) of water equivalent to an absolute pressure of 6.06 lb/in^2 (0.42 bar abs), the axial force caused by the overhung impeller and acting toward the suction will be only 27 lb (121 N). On the other hand, if the suction pressure is 100 lb/in^2 (6.89 bar), the force will be 314 lb (1405 N) and will act in the opposite direction. Therefore, because the same pump may be used under many conditions over a wide range of suction pressures, the thrust bearing of pumps with single-suction, overhung impellers must be arranged to take the thrust in either direction. They must also be selected with a sufficient thrust capacity to counteract forces set up under the maximum suction pressure established for that particular pump.

This extra thrust capacity can become quite significant in certain special cases, such as with boiler circulating pumps. These are usually of the single-suction, single-stage, overhung impeller type and may be exposed to suction pressures as high as 2800 lb/in^2 gage (193 bar). This is approximately the vapor pressure of 685°F (363°C) boiler water. If such a pump has a shaft diameter of 6-in (15.24 cm), the unbalanced thrust would be as much as 77,500 lb (346,770 N), and the thrust bearing has to be capable of counteracting this.

Axial Thrust of Single-Suction Semiopen Radial-Flow Impellers The axial thrust generated in semiopen impellers is higher than that in closed impellers. This is illustrated in Figure 58, which shows that the pressure on the open side of the impeller varies from essentially the discharge pressure at the periphery (at diameter D_2) to the suction pressure at the impeller eye (at diameter D_1). The pressure distribution on the back shroud is essentially the same as that illustrated in Figure 54, varying from discharge pressure at the periphery to some portion of this pressure at the impeller hub. This latter pressure is, of course, substantially higher than the suction pressure. The unbalanced portion of the axial thrust on the impeller is represented by the cross-hatched area in Figure 58.

One of the means available for partially balancing this increased axial thrust is to provide the back shroud with pump-out vanes, as in Figures 37 and 56.

Fully open impellers or semiopen impellers with a portion of the back shroud removed produce an axial thrust somewhat higher than closed impellers and somewhat lower than semiopen impellers.

Axial Thrust of Mixed-Flow and Axial-Flow Impellers The axial thrust in radial impellers is produced by the static pressures on the impeller shrouds. Axial-flow impellers have no shrouds, and the axial thrust is created strictly by the difference in pressure on the two faces of the impeller vanes. In addition, a difference may exist in pressure acting on the two shaft hub ends, one generally subject to discharge pressure and the other to suction pressure.

With mixed-flow impellers, axial thrust is a combination of forces caused by the action of the vanes on the liquid and those arising from the difference in the pressures acting on the various surfaces. Wearing rings are often provided on the back of mixed-flow impellers, with either balancing holes through the impeller hub or an external balancing pipe leading back to the suction.

FIGURE 58 Axial thrust in a semiopen single-suction impeller

FIGURE 59 Multistage pump with single-suction impellers facing in one direction and hydraulic balancing device (Flowserve Corporation)

FIGURE 60 A four-stage pump with opposed impellers (Flowserve Corporation)

Except for very large units and in certain special applications, the axial thrust developed by mixed-flow and axial-flow impellers is carried by thrust bearings with the necessary load capacity.

Axial-Thrust in Multistage Pumps Most multistage pumps are built with single-suction impellers in order to simplify the design of the interstage connections. Two obvious arrangements are possible for the single-suction impellers:

1. Several single-suction impellers can be mounted on one shaft, each having its suction inlet facing in the same direction and its stages following one another in ascending order of pressure (see Figure 59). The axial thrust is then balanced by a hydraulic balancing device.
2. An even number of single-suction impellers can be used, one-half facing in one direction and the other half facing in the opposite direction. With this arrangement, an axial thrust on the first half is compensated by the thrust in the opposite direction on the other half (see Figure 60). This mounting of single-suction impellers back to back is frequently called *opposed impellers*.

An uneven number of single-suction impellers can be used with this arrangement, provided the correct shaft and interstage bushing diameters are used to give the effect of a hydraulic balancing device that will compensate for the hydraulic thrust on one of the stages.

It is important to note that the opposed impeller arrangement completely balances an axial thrust only under the following conditions:

- The pump must be provided with two seal chambers.
- The shaft must have a constant diameter.
- The impeller hubs must not extend through the interstage portion of the casing separating adjacent stages.

Except for some special pumps that have an internal and enclosed bearing at one end, and therefore only one seal chamber, most multistage pumps fulfill the first condition. Because of structural requirements, however, the last two conditions are not practical. A slight residual thrust is usually present in multistage opposed impeller pumps and is carried on the thrust bearing.

HYDRAULIC BALANCING DEVICES

If all the single-suction impellers of a multistage pump face the same direction, the total theoretical hydraulic axial thrust acting toward the suction end of the pump will be the sum of the individual impeller thrusts. The thrust magnitude will be approximately equal to the product of the net pump pressure and the annular unbalanced area. Actually, the axial thrust turns out to be about 70 to 80 percent of this theoretical value.

Some form of hydraulic balancing device must be used to balance this axial thrust and to reduce the pressure on the seal chamber adjacent to the last-stage impeller. This hydraulic balancing device may be a balancing drum, a balancing disk, or a combination of the two.

Balancing Drums The balancing drum is illustrated in Figure 61. The balancing chamber at the back of the last-stage impeller is separated from the pump interior by a drum that is usually keyed to the shaft and rotates with it. The drum is separated by a small radial clearance from the stationary portion of the balancing device, called the *balancing-drum head*, or balancing sleeve, which is fixed to the pump casing.

The balancing chamber is connected either to the pump suction or to the vessel from which the pump takes its suction. Thus, the back pressure in the balancing chamber is only slightly higher than the suction pressure, the difference between the two being equal to the friction losses between this chamber and the point of return. The leakage between

FIGURE 61 Balancing drum

the drum and the drum head is, of course, a function of the differential pressure across the drum and of the clearance area.

The forces acting on the balancing drum in Figure 61 are the following:

- *Toward the discharge end:* the discharge pressure multiplied by the front balancing area (area *B*) of the drum
- *Toward the suction end:* the back pressure in the balancing chamber multiplied by the back balancing area (area *C*) of the drum

The first force is greater than the second, thereby counterbalancing the axial thrust exerted upon the single-suction impellers. The drum diameter can be selected to balance the axial thrust completely or within 90 to 95 percent, depending on the desirability of carrying any thrust-bearing loads.

It has been assumed in the preceding simplified description that the pressure acting on the impeller walls is constant over their entire surface and that the axial thrust is equal to the product of the total net pressure generated and the unbalanced area. Actually, this pressure varies somewhat in the radial direction because of the centrifugal force exerted upon the liquid by the outer impeller shroud (refer to Figure 54). Furthermore, the pressures at two corresponding points on the opposite impeller faces (*D* and *E* in Figure 61) may not be equal because of a variation in clearance between the impeller wall and the casing section separating successive stages. Finally, a pressure distribution over the impeller wall surface may vary with head and capacity operating conditions.

This pressure distribution and design data can be determined quite accurately for any one fixed operating condition, and an effective balancing drum could be designed on the basis of the forces resulting from this pressure distribution. Unfortunately, varying head and capacity conditions change the pressure distribution, and as the area of the balancing drum is necessarily fixed, the equilibrium of the axial forces can be destroyed.

The objection to this is not primarily the amount of the thrust, but rather that the direction of the thrust cannot be predetermined because of the uncertainty about internal pressures. Still it is advisable to predetermine normal thrust direction, as this can influence external mechanical thrust-bearing design. Because 100 percent balance is unattainable in practice and because the slight but predictable unbalance can be carried on a thrust bearing, the balancing drum is often designed to balance only 90 to 95 percent of the total impeller thrust.

The balancing drum satisfactorily balances the axial thrust of single-suction impellers and reduces pressure on the discharge-side stuffing box. It lacks, however, the virtue of automatic compensation for any changes in axial thrust caused by varying impeller reaction characteristics. In effect, if the axial thrust and balancing drum forces become unequal, the rotating element will tend to move in the direction of the greater force. The thrust bearing must then prevent excessive movement of the rotating element. The balancing drum performs no restoring function until such time as the drum force again equals the axial thrust. This automatic compensation is the major feature that differentiates the balancing disk from the balancing drum.

Balancing Disks The operation of the simple balancing disk is illustrated in Figure 62. The disk is fixed to and rotates with the shaft. It is separated by a small axial clearance from the balancing disk head, or balancing sleeve, which is fixed to the casing. The leakage through this clearance flows into the balancing chamber and from there either to the pump suction or to the vessel from which the pump takes its suction. The back of the balancing disk is subject to the balancing chamber back pressure, whereas the disk face experiences a range of pressures. These vary from discharge pressure at its smallest diameter to back pressure at its periphery. The inner and outer disk diameters are chosen so that the difference between the total force acting on the disk face and that acting on its back will balance the impeller axial thrust.

If the axial thrust of the impellers should exceed the thrust acting on the disk during operation, the latter is moved toward the disk head, reducing the axial clearance between

FIGURE 62 A simple balancing disk

the disk and the disk head. The amount of leakage through the clearance is reduced so that the friction losses in the leakage return line are also reduced, lowering the back pressure in the balancing chamber. This lowering of pressure automatically increases the pressure difference acting on the disk and moves it away from the disk head, increasing the clearance. Now the pressure builds up in the balancing chamber, and the disk is again moved toward the disk head until an equilibrium is reached.

To assure proper balancing in disk operation, the change in back pressure in the balancing chamber must be of an appreciable magnitude. Thus, with the balancing disk wide open with respect to the disk head, the back pressure must be substantially higher than the suction pressure to give a resultant force that restores the normal disk position. This can be accomplished by introducing a restricting orifice in the leakage return line that increases back pressure when leakage past the disk increases beyond normal. The disadvantage of this arrangement is that the pressure on the seal chamber is variable, a condition that may be injurious to the life of the seal and therefore should be avoided.

Combination Balancing Disk and Drum For the reasons just described, the simple balancing disk is seldom used. The combination balancing disk and drum (see Figure 63) was developed to obviate the shortcomings of the disk while retaining the advantage of automatic compensation for axial thrust changes.

The rotating portion of this balancing device consists of a long cylindrical body that turns within a drum portion of the disk head. This rotating part incorporates a disk similar to the one previously described. In this design, radial clearance remains constant regardless of disk position, whereas the axial clearance varies with the pump rotor position. The following forces act on this device:

- *Toward the discharge end:* the sum of the discharge pressure multiplied by area A , plus the average intermediate pressure multiplied by area B
- *Toward the suction end:* the back pressure multiplied by area C

Whereas the position-restoring feature of the simple balancing disk required an undesirably wide variation of the back pressure, it is now possible to depend upon a variation of the intermediate pressure to achieve the same effect. Here is how it works: When the pump rotor moves toward the suction end (to the left in Figure 63) because of increased axial thrust, the axial clearance is reduced and pressure builds up in the intermediate

FIGURE 63 A combination balancing disk and drum

relief chamber, increasing the average value of the intermediate pressure acting on area *B*. In other words, with reduced leakage, the pressure drop across the radial clearance decreases, increasing the pressure drop across the axial clearance. The increase in intermediate pressure forces the balancing disk toward the discharge end until equilibrium is reached. Movement of the pump rotor toward the discharge end would have the opposite effect, increasing the axial clearance and the leakage and decreasing the intermediate pressure acting on area *B*.

Now numerous hydraulic balancing device modifications are in use. One typical design separates the drum portion of a combination device into two halves, one preceding and the second following the disk (see Figure 64). The virtue of this arrangement is a definite cushioning effect at the intermediate relief chamber, thus avoiding too positive a restoring action, which might result in the contacting and scoring of the disk faces.

SHAFTS AND SHAFT SLEEVES

The basic function of a centrifugal pump shaft is to transmit the torques encountered when starting and during operation while supporting the impeller and other rotating parts. It must do this job with a deflection less than the minimum clearance between rotating and stationary parts. The loads involved are (1) the torques, (2) the weight of the parts, and (3) both radial and axial hydraulic forces. In designing a shaft, the maximum allowable deflection, the span or overhang, and the location of the loads all have to be considered, as does the critical speed of the resulting design.

Shafts are usually proportioned to withstand the stress set up when a pump is started quickly, such as when the driving motor is energized directly across the line. If the pump handles hot liquids, the shaft is designed to withstand the stress set up when the unit is started cold without any preliminary warmup.

Critical Speeds Any object made of an elastic material has a natural period of vibration. When a pump rotor or shaft rotates at any speed corresponding to its natural frequency, minor unbalances will be magnified. These speeds are called the *critical speeds*.

In conventional pump designs, the rotating assembly is theoretically uniform around the shaft axis and the center of mass should coincide with the axis of rotation. This theory does not hold for two reasons. First, minor machining or casting irregularities always occur. Second, variations exist in the metal density of each part. Thus, even in vertical-shaft machines having no radial deflection caused by the weight of the parts, this eccentricity of the center of mass produces a centrifugal force and therefore a deflection when

FIGURE 64 A combination balancing disk and drum with a disk located in the center portion of the drum (Flowserve Corporation)

the assembly rotates. At the speed where the centrifugal force exceeds the elastic restoring force, the rotor will vibrate as though it were seriously unbalanced. If it is run at that speed without restraining forces, the deflection will increase until the shaft fails.

Rigid and Flexible Shaft Designs The lowest critical speed is called the first critical speed, the next highest is called the second, and so forth. In centrifugal pump nomenclature, a *rigid shaft* means one with an operating speed lower than its first critical speed. A *flexible shaft* is one with an operating speed higher than its first critical speed. Once an operating speed has been selected, relative shaft dimensions must still be determined. In other words, it must be decided whether the pump will operate above or below the first critical speed.

Actually, the shaft critical speed can be reached and passed without danger because frictional forces tend to restrain the deflection. These forces are exerted by the surrounding liquid, and the various internal leakage joints acting as internal liquid-lubricated bearings. Once the critical speed is passed, the pump will run smoothly again up to the second speed corresponding to the natural rotor frequency, and so on to the third, fourth, and all higher critical speeds.

Designs rated for 1,750 rpm (or lower) are usually of the rigid-shaft type. On the other band, high-head 3,600 rpm (or higher) multistage pumps, such as those in a boiler-feed service, are frequently of the flexible-shaft type. It is possible to operate centrifugal pumps above their critical speeds for the following two reasons: (1) very little time is required to attain full speed from rest (the time required to pass through the critical speed must therefore be extremely short) and (2) the pumped liquid in the internal leakage joints acts as a restraining force on the vibration.

Experience has proved that, although it was usually assumed necessary to use shafts of such rigidity that the first critical speed is at least 20 percent above the operating speed, equally satisfactory results can be obtained with lighter shafts with a first critical speed of about 60 to 75 percent of the operating speed. This, it is felt, is a sufficient margin to avoid any danger caused by an operation close to the critical speed.

Influence of Shaft Deflection To understand the effect of critical speed on the selection of shaft size, consider the fact that the first critical speed of a shaft is linked to its static deflection. Shaft deflection depends upon the weight of the rotating element (w), the shaft span (l), and the shaft diameter (d). The basic formula is as follows:

$$f = \frac{wl^3}{CEI}$$

where f = deflection, in (m)

w = weight of the rotating element, lb (N)

l = shaft span, in (m)

C = coefficient depending on shaft-support method and load distribution

E = modulus of elasticity of shaft materials, lb/in² (N/m²)

I = moment of inertia ($\pi d^4/64$) in⁴ (m⁴)

This formula is given in its most simplified form, that is, for a shaft of constant diameter. If the shaft is of varying diameter (the usual situation), deflection calculations are much more complex. A graphical deflection analysis may then be the most practical answer.

This formula works only for static deflection, the only variable that affects critical speed calculations. The actual shaft deflection, which must be determined to establish minimum permissible internal clearances, must take into account all transverse hydraulic reactions on the rotor, the weights of the rotating element, and other external loads.

It is not necessary to calculate the exact deflection to make a relative shaft comparison. Instead, a factor can be developed that will be representative of relative shaft deflections. As a significant portion of rotor weight is in the shaft, and as methods of bearing support and the modulus of elasticity are common to similar designs, deflection f can be shown as follows:

$$f = \text{function of } \frac{(ld^2)(l^3)}{d^4}$$

$$f = \text{function of } \frac{l^4}{d^2}$$

In other words, pump deflection varies approximately as the fourth power of the shaft span and inversely as the square of shaft diameter. Therefore, the lower the l^4/d^2 factor for a given pump, the lower the unsupported shaft deflection, essentially in proportion to this factor.

For practical purposes, the first critical speed N_c can be calculated as

$$\text{in USCS units} \quad N_c = \frac{187.7}{\sqrt{f(\text{in})}} \text{ rpm}$$

$$\text{in SI units} \quad N_c = \frac{946}{\sqrt{f(\text{mm})}} \text{ rpm}$$

To maintain internal clearances at the wearing rings, it is usually desirable to limit the shaft deflection under the most adverse conditions to between 0.005 and 0.006 in (0.127 and 0.152 mm). It follows that a shaft design with a deflection of 0.005 to 0.006 in will have a first critical speed of 2,400 to 2,650 rpm. This is the reason for using rigid shafts for pumps that operate at 1,750 rpm or lower. Multistage pumps operating at 3,600 rpm or higher use shafts of equal stiffness (for the same purpose of avoiding wearing ring contact). However, their corresponding critical speed is about 25 to 40 percent less than their operating speed.

Lomakin Effect All the previous material refers to the behavior of a rotor and its shaft operating in air. In reality, the rotor operates immersed in the liquid being pumped, and this liquid flows through one or more of the small annular areas created by clearances separating regions in the pump under different pressures, such as at the wearing rings, interstage bushings, or balancing devices. This flow of liquid creates what is called a *hydrodynamic bearing effect* and essentially transforms the rotor from one supported at two bearings external to the pump to one with several additional internal bearings lubricated by the liquid pumped. This phenomenon is generally called the *Lomakin effect*.

The result of the Lomakin effect is that the deflection of the shaft when a pump is running is reduced somewhat from the value calculated for the shaft operating in air and the critical speed is increased. The advantage of this effect, particularly in the design of some multistage pumps, is that it permits the use of longer and more slender shafts. Whether this is sound practice remains a controversial subject. The supportive effect of the hydrodynamic bearings depends on (a) the pressure differential, which disappears completely when the pump is at rest, and (b) the clearance, which decreases substantially as the internal clearances increase with erosive or contact wear. Thus, contact between rotating and stationary parts will take place every time a pump is started if the internal clearances are initially less than the shaft deflection in air. This contact will again take place as the pump coasts down after being stopped. Furthermore, as wear takes place at the running joints, the shaft assumes a deflection closer and closer to its deflection in air, unsupported by the Lomakin effect.

In view of all these facts, it is recommended that pump users acquaint themselves not only with the calculated shaft deflections with a pump running in new condition, but also with the shaft deflections in air. This way they can compare these with the internal clearances.

Shaft Sizing Shaft diameters are usually larger than what is actually needed to transmit the torque. A factor that assures this conservative design is a requirement for ease of rotor assembly.

The shaft diameter must be stepped up several times from the end of the coupling to its center to facilitate impeller mounting (see Figure 65). Starting with the maximum diameter at the impeller mounting, there is a step down for the shaft sleeve and another for the external shaft nut, followed by several more for the bearings and the coupling. Therefore, the shaft diameter at the impellers exceeds that required for torsional strength at the coupling by at least an amount sufficient to provide all intervening step downs.

One frequent exception to shaft oversizing at the impeller occurs in units consisting of two double-suction, single-stage pumps operating in a series, one of which is fitted with a

FIGURE 65 Rotor assembly of a single-stage, double-suction pump (Flowservice Corporation)

double-extended shaft. As this pump must transmit the total horsepower for the entire series unit, the shaft diameter at its inboard bearing may have to be larger than normal.

The shaft design of end-suction, overhung impeller pumps presents a somewhat different problem. One method for reducing shaft deflection at the impeller and seal chamber, where the concentricity of running fits is extremely important, is to considerably increase the shaft diameter between the bearings.

Except in certain smaller sizes, centrifugal pump shafts are protected against wear, erosion, and corrosion by renewable shaft sleeves. In small pumps, however, shaft sleeves present a certain disadvantage. As the sleeve cannot appreciably contribute to shaft strength, the shaft itself must be designed for the full maximum stress. Shaft diameter is then materially increased by the addition of the sleeve, as the sleeve thickness cannot be decreased beyond a certain safe minimum. The impeller suction area may therefore become dangerously reduced, and if the eye diameter is increased to maintain a constant eye area, the liquid pickup speed must be increased unfavorably. Other disadvantages accrue from greater hydraulic and seal losses caused by increasing the effective shaft diameter out of proportion to the pump size.

To eliminate these shortcomings, very small pumps frequently use shafts of stainless steel or some other material that is sufficiently resistant to corrosion and wear that it does not need shaft sleeves. One such pump is illustrated in Figure 66. Manufacturing costs, of course, are much less for this type of design, and the cost of replacing the shaft is about the same as the cost of new sleeves (including installation).

Shaft Sleeves Pump shafts are usually protected from erosion, corrosion, and wear at seal chambers, leakage joints, internal bearings, and in the waterways by renewable sleeves.

The most common shaft sleeve function is that of protecting the shaft from wear at packing and mechanical seals. Shaft sleeves serving other functions are given specific names to indicate their purpose. For example, a shaft sleeve used between two multistage pump impellers in conjunction with the interstage bushing to form an interstage leakage joint is called an *interstage* or *distance sleeve*.

In medium-size centrifugal pumps with two external bearings on opposite sides of the casing (the common double-suction and multistage varieties), the favored shaft sleeve construction uses an external shaft nut to hold the sleeve in an axial position against the impeller hub. Sleeve rotation is prevented by a key, usually an extension of the impeller key (see Figure 67). The axial thrust of the impeller is transmitted through the sleeve to the external shaft nut.

In larger high-head pumps, a high axial load on the sleeve is possible and a design similar to that shown in Figure 68 may be preferred. This design has the advantages of simplicity and ease of assembly and maintenance. It also provides space for a large seal chamber

FIGURE 66 Section of a small centrifugal pump with no shaft sleeves (Flowserve Corporation)

FIGURE 67 A sleeve with external locknut and impeller key extending into the sleeve to prevent rotation

FIGURE 68 A sleeve with an internal impeller nut, external shaft-sleeve nut, and a separate key for the sleeve

FIGURE 69 A sleeve threaded onto a shaft with no external locknut

and cartridge-type mechanical seals. When shaft sleeve nuts are used to retain the sleeves and impellers axially, they are usually manufactured with right- and left-hand threads. The friction of the pumpage and inadvertent contact with stationary parts or bushings will tend to tighten the nuts against the sleeve and impeller hub (rather than loosen them). Usually, the shaft sleeves utilize extended impeller keys to prevent rotation.

Some manufacturers favor the sleeve shown in Figure 69, in which the impeller end of the sleeve is threaded and screwed to a matching thread on the shaft. A key cannot

be used with this type of sleeve, and right- and left-hand threads are substituted so that the frictional grip of the packing on the sleeve will tighten it against the impeller hub. As a safety precaution, the external shaft nuts and the sleeve itself use set screws for a locking device.

In pumps with overhung impellers, various types of sleeves are used. Most pumps use mechanical seals, and the shaft sleeve is usually a part of the mechanical seal package supplied by the seal manufacturer. Many mechanical seals are of the cartridge design, which is set and may be bench-tested for leakage prior to installation in the pump. (For a further discussion of mechanical seals, see Subsection 2.2.3.)

For overhung impeller pumps that utilize packing for sealing, the packing sleeves generally extend from the impeller hub through the seal chambers (or stuffing boxes) to protect the pump shaft from wear (see Figure 70). The sleeves are usually keyed to the shaft to prevent rotation. If a hook-type sleeve is used, the hook part of the sleeve is clamped between the impeller and a shaft shoulder to maintain the axial position of the sleeve. A hook-type sleeve used to be popular for overhung impeller pumps that operate at high temperatures because it is clamped at the impeller end and the rest of the sleeve is free to expand axially with temperature changes. But with the increased use of cartridge-type seals, the use of hook-type sleeves is diminishing.

In designs with a metal-to-metal joint between the sleeve and the impeller hub or shaft nut, a sealing device is required between the sleeve and the shaft to prevent leakage. Pumped liquid can leak into the clearance between the shaft and the sleeve when operating under a positive suction head and air can leak into the pump when operating under a negative suction head. This seal can be accomplished by means of an *O-ring*, as shown in Figure 71, or a flat gasket. For high temperature services, the sealing device must be either acceptable for the temperature to which it will be exposed, or it must be located outside the high temperature liquid environment. An alternative design used for some high-temperature process pumps is shown in Figure 72. In this arrangement, the contact surface of the hook-type sleeve and the shaft is ground at a 45-degree angle to form a metal-to-metal seal. That end of the sleeve is locked, but the other is *free* to expand with temperature changes.

When O-rings are used, any sealing surfaces must be properly finished to ensure a positive seal is achieved. All bores and changes in diameter over which O-rings must be passed should be properly radiused and chamfered to protect against damage during assembly. Guidelines for assembly dimensions and surface finish criteria are listed in O-ring manufacturers' catalogs.

Material for Packing Sleeves Packing sleeves are surrounded in the stuffing box by packing. The sleeve must be smooth so that it can turn without generating too much friction and heat. Thus, the sleeve materials must be capable of taking a very fine finish, preferably a polish. Cast-iron is therefore not suitable. A hard bronze is generally used for pumps handling clear water, but chrome or other stainless steels are sometimes pre-

FIGURE 70 A sleeve for pumps with an overhung impeller

FIGURE 71 A seal arrangement for the shaft sleeve to prevent leakage along the shaft

FIGURE 72 A sleeve with a 45° bevel contacting surface

ferred. For pumps subject to abrasives, hardened chrome or other stainless steels give good results. In most applications, a hardened chromium steel sleeve will be technically adequate, and the most economical choice. For severe or unusual conditions, coated sleeves are used. Ceramic coatings, applied using a plasma spray process, have also been used. Chromium oxide and aluminum oxide are the most common ceramic coatings. Both are extremely hard and resist abrasive wear well.

Ceramic coatings have been replaced in some applications by tungsten carbide coatings applied using a *high-velocity oxyfuel* (HVOF) process. The superior impact resistance and bond strength of these coatings is well documented. Another coating that is widely used on pump sleeves is a nickel-chromium-silicon-boron self-fluxing coating. This coating has a good resistance to galling and moderate resistance to abrasive wear.

Sleeves intended for coating should be machined with an undercut, so that the coating does not extend to the edge of the sleeve. This will prevent chipping at the edge, especially with the more brittle ceramic coatings.

SEAL CHAMBERS AND STUFFING BOXES

Seal chambers have the primary function of protecting the pump against leakage at the point where the shaft passes out through the pump pressure casing. If the pump handles a suction lift and the pressure at the bottom of the seal chamber (the point closest to the inside of the pump) is below atmospheric, the seal chamber function is to prevent air leakage into the pump. If this pressure is above atmospheric, the function is to prevent liquid leakage out of the pump.

FIGURE 73 A conventional stuffing box with throat bushing

FIGURE 74 A conventional stuffing box with a bottoming ring

FIGURE 75 A lantern ring (also called a seal cage)

When sealing is accomplished by means of a mechanical seal, the seals are installed in a *seal chamber*. When sealing is accomplished by means of packing, the seal chamber is commonly referred to as a *stuffing box*. For general service pumps, a stuffing box usually takes the form of a cylindrical recess that accommodates a number of rings of packing around the shaft or shaft sleeve (see Figures 73 and 74). If sealing the box is desired, a lantern ring or seal cage (see Figure 75) is used to separate the rings of packing into approximately equal sections. The packing is compressed to give the desired fit on the

shaft or sleeve by a gland that can be adjusted in an axial direction. The bottom or inside end of the box can be formed by the pump casing (refer to Figure 70), a throat bushing (see Figure 78), or a bottoming ring (see Figure 74).

For manufacturing reasons, throat bushings are widely used on smaller pumps with axially split casings. Throat bushings are always solid rather than split. The bushing is usually held from rotation by a tongue-and-groove joint locked in the lower half of the casing.

Packing Lantern Rings (Seal Cages) When a pump operates with negative suction head, the inner end of the stuffing box is under vacuum and air tends to leak into the pump. For this type of service, packing is usually separated into two sections by a lantern ring or seal cage (refer to Figure 73).

Water or some other sealing fluid is introduced under pressure into the lantern ring connection, causing a flow of sealing fluid in both axial directions. This construction is useful for pumps handling chemically active or dangerous liquids since it prevents an outflow of the pumped liquid. Lantern rings are usually axially split for ease of assembly.

Some installations involve variable suction conditions, the pump operating part of the time with suction head and part of the time with suction lift. When the operating pressure inside the pump exceeds atmospheric pressure, the liquid lantern ring becomes inoperative (except for lubrication). However, it is maintained in service so that when the pump is primed at starting, all air can be excluded.

Sealing Liquid Arrangements When a pump handles clean, cool water, sealing liquid connections are usually to the pump discharge or, in multistage pumps, to an intermediate stage. An independent supply of sealing water should be provided if any of the following conditions exist:

- A suction lift in excess of 15 ft (4.5 m)
- A discharge pressure under 10 lb/in² (0.7 bar)
- Hot water (over 250°F or 120°C) being handled without adequate cooling (except for boiler-feed pumps, in which lantern rings are not used)
- Muddy, sandy, or gritty water being handled
- The pump is a hot-well pump.
- The liquid being handled is other than water, such as acid, juice, molasses, or sticky liquids, without special provision in the stuffing box design for the nature of the liquid

If the suction lift exceeds 15 ft (4.5 m), excessive air infiltration through the stuffing boxes may make priming difficult unless an independent seal is provided. A discharge pressure under 10 lb/in² (0.7 bar) may not provide sufficient sealing pressure. Hot-well (or condensate) pumps operate with as much as a 28-in Hg (710 mm Hg) vacuum, and air infiltration would take place when the pumps are standing idle in standby service.

When sealing water is taken from the pump discharge, an external connection may be made through small-diameter piping (see Figure 76) or internal passages. In some pumps, these connections are arranged so that a sealing liquid can be introduced into the packing space through an internal drilled passage either from the pump casing or from an external source (see Figure 77). When the liquid pumped is used for sealing, the external connection is plugged. If an external sealing liquid source is required, it is connected to the external pipe tap with a socket-head pipe plug inserted at the internal pipe tap.

It is sometimes desirable to locate the lantern ring with more packing on one side than on the other. For example, in gritty-water services, a lantern ring location closer to the inner portion of the pump would divert a greater proportion of sealing liquid into the pump, thereby keeping grit from working into the box. An arrangement with most of the packing rings between the lantern ring and the inner end of the stuffing box would be applied to reduce dilution of the pumped liquid.

Some pumps handle water in which there are small, even microscopic, solids. Using water of this kind as a sealing liquid introduces the solids into the leakage path, shortening the life of the packing and sleeves. It is sometimes possible to remove these solids

FIGURE 76 Piping connections from the pump discharge to seal cages

FIGURE 77 An end-suction pump with provisions for an internal or external sealing-liquid supply (Flowserve Corporation)

by installing small pressure filters in the sealing water piping from the casing to the stuffing box.

Filters ultimately get clogged, though, unless they are frequently backwashed or otherwise cleaned out. This disadvantage can be overcome by using a cyclone (or centrifugal) separator. The operating principle of the cyclone separator is based on the fact that if a liquid under pressure is introduced tangentially into a vortexing chamber, a centrifugal force will make it rotate in the chamber, creating a vortex. Particles heavier than the liquid in which they are carried will hug the outside wall of the vortexing chamber and the liquid in the center of the chamber will be relatively free of foreign matter. The action of such a separator is illustrated in Figure 78. Liquid piped from the pump discharge or from an intermediate stage of a multistage pump is piped to inlet tap A, which is drilled tangentially to the cyclone bore. The liquid containing solids is directed downward to the apex of the cone at outlet tap B and is piped to the suction or to a low-pressure point in the system. The cleaned liquid is taken off at the center of the cyclone at outlet tap C and is piped to the stuffing box.

Sand that will pass through a No. 40 sieve will be completely eliminated in a cyclone separator with supply pressures as low as 20 lb/in² (1.4 bar). With 100 lb/in² (7-bar) supply pressure, 95 percent of the particles of 5-micron size will be eliminated.

FIGURE 78 An illustration of the principle of cyclone separators (Flowsolve Corp.)

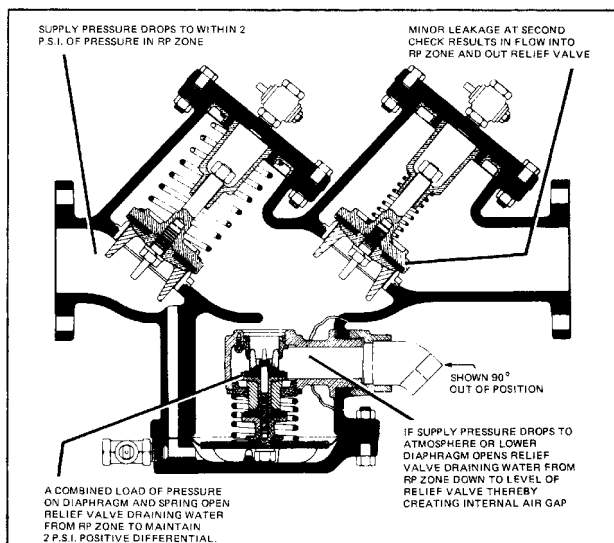

FIGURE 79 Backflow preventer (Hersey Products)

Most city ordinances require that some form of backflow preventer be interposed between city water supply lines and connections to equipment where backflow or siphoning could contaminate a drinking water supply.

This is the case, for instance, with an independent sealing supply used for stuffing boxes of sewage pumps. Quite a variety of backflow preventers are available. In most cases, the device consists of two spring-loaded check valves in a series and a spring-loaded, diaphragm-actuated, differential-pressure relief valve located in the zone between the check valves (see Figure 79).

In a normal operation, both check valves remain open as long as there is a demand for sealing water. The differential-pressure relief valve remains closed because of the pressure drop past the first check valve. If the pressure downstream of the device increases, tending to reverse the direction of the flow, both check valves close and prevent backflow. If the second check valve is prevented from closing tightly, the leakage past it increases the pressure between the two check valves, the relief valve opens, and water is discharged to the

FIGURE 80 A water seal unit

FIGURE 81 A weighted grease sealer

atmosphere. Thus, the relief valve operates automatically to maintain the pressure between the two check valves lower than the supply pressure.

Some local ordinances prohibit any connections between city water lines and a sewage or process liquid line. In such cases, an open tank under atmospheric pressure is installed into which city water can be admitted and from which a small pump can deliver the required quantity of sealing water. Such a water-sealing supply unit (see Figure 80) can be installed in a location where it can serve a number of pumps.

The tank is equipped with a float valve to feed and regulate the water level so that contamination of the city water supply is prevented. A small close-coupled pump is mounted directly on the tank and maintains a constant pressure of clear water at the stuffing box seals of the battery of pumps it serves. A small recirculation line is provided from the close-coupled pump discharge back to the tank to prevent operation at shutoff. The discharge pressure of the small supply pump is set by the maximum sealing pressure required at any of the pumps served. The supply at the individual stuffing boxes is then regulated by setting small control valves in each individual line.

If clean, cool water is not available (as with some drainage, irrigation, or sewage pumps), grease or oil seals are often used. Most pumps for sewage service have a single stuffing box subject to discharge pressure that operates with a flooded suction. It is therefore not necessary to seal these pumps against air leakage, but forcing grease or oil into the sealing space at the packing helps to exclude grit. Figure 81 shows a typical weighted grease sealer.

FIGURE 82 An automatic grease sealer mounted on a vertical pump (Zimmer & Francescon)

Automatic grease or oil sealers that exert pump discharge pressure in a cylinder on one side of a plunger, with light grease or oil on the other side, are available for sewage service. The oil or grease line is connected to the stuffing box seal, which is at about 80 percent of the discharge pressure. As a result, there is a slow flow of grease or oil into the pump when the unit is in operation. No flow takes place when the pump is out of service. Figure 82 shows an automatic grease sealer mounted on a vertical sewage pump.

Water-Cooled Stuffing Boxes High temperatures or pressures complicate the problem of maintaining stuffing box packing. Pumps in these more difficult services are usually provided with mechanical seals and seal support systems. When it is necessary or desirable to use packing, however, the pumps are usually equipped with jacketed, water-cooled stuffing boxes. The cooling water removes heat from the liquid leaking through the stuffing box and heat generated by friction in the box, thus improving packing service conditions. In some special cases, liquid other than water can be used in the cooling jackets. Two water-cooled stuffing box designs are commonly used. The first, shown in Figure 83, provides cored passes in the casing casting. These passages that surround the stuffing box are arranged with in-and-out connections. The second type uses a separate cooling chamber combined with the stuffing box proper, with the whole assembly inserted into and bolted to the pump casing (see Figure 84). The choice between the two is based on manufacturing preferences.

Caution is required when depending on water cooling to provide proper operation because of the danger of passage fouling and a loss of cooling effectiveness during operation. It is important that any such cooling passages be accessible for periodic inspection and cleaning to ensure that effective cooling is maintained.

Stuffing box pressure and temperature limitations vary with the pump type because it is generally not economical to use expensive stuffing box construction for infrequent high-temperature or high-pressure applications. Therefore, whenever the manufacturer's stuffing box limitations for a given pump are exceeded, the application of pressure-reducing devices ahead of the stuffing box is recommended.

Pressure-Reducing Devices Essentially, pressure-reducing devices consist of a bushing or meshing labyrinth ending in a relief chamber located between the pump interior and the stuffing box or seal chamber. The relief chamber is connected to some suitable

FIGURE 83 A water-cooled stuffing box with a cored water passage cast in casing

FIGURE 84 A separate water-cooled stuffing box with pressure-reducing stuffing box bushing

low-pressure point in the installation, and the leakage past the pressure-reducing device is returned to this point. If the pumped liquid must be salvaged, as with treated feedwater, it is returned to the pumping cycle. If the liquid is expendable, the relief chamber can be connected to a drain.

Many different pressure-reducing device designs exist. Figure 84 illustrates a design for limited pressures. A short serrated bushing is inserted at the bottom of the stuffing box or seal chamber, followed by a relief chamber. The leakage past the serrated bushing is bled off to a low-pressure point.

FIGURE 85 Split stuffing box gland

With relatively high-pressure units, intermeshing labyrinths can be located following the balancing device and ahead of the stuffing box or seal chamber. Piping from the chamber following pressure-reducing devices should be amply sized so that as wear increases leakage, piping friction will not increase seal chamber pressure.

Stuffing Box Packing Glands Stuffing box packing glands may assume several forms, but basically they can be classified into two groups: solid glands and split glands (see Figure 85). Split glands are made in halves so that they can be removed from the shaft without dismantling the pump, thus providing more working space when the stuffing boxes are being repacked. Split glands are desirable for pumps that have to be repacked frequently, especially if the space between the box and the bearing is restricted. The two halves are generally held together by bolts, although other methods are also used. Split glands are generally a construction refinement rather than a necessity, and they are rarely used in smaller pumps. They are commonly furnished for large single-stage pumps, for some multistage pumps, and for certain refinery pumps.

Another common refinement is the use of swing bolts in stuffing box packing glands. Such bolts may be swung to the side, out of the way, when the stuffing box is being repacked.

Stuffing box leakage into the atmosphere might, in some services, seriously inconvenience or even endanger the operating personnel. An example would be when volatile liquids are being pumped at vaporizing temperatures or temperatures above their flash point. As this leakage cannot always be cooled sufficiently by a water-cooled stuffing box, smothering glands are used (refer to Figure 83). Provisions are made in the gland to introduce a liquid, either water or another compatible liquid at a low temperature, that mixes intimately with the leakage, lowering its temperature or, if the liquid is volatile, absorbing it.

Stuffing box packing glands are usually made of bronze, although cast-iron or steel may be used for all iron-fitted pumps. Iron or steel glands are generally bushed with a non-sparking material like bronze in hazardous process services to prevent the ignition of flammable vapors by the glands sparking against a ferrous metal shaft or sleeve.

Stuffing Box Packing See Subsection 2.2.2.

MECHANICAL SEALS VERSUS PACKING

Sealing with a packed stuffing box is impractical for many conditions of service. In an ordinary packed stuffing box, the sealing between the rotating shaft or shaft sleeve and the stationary portion of the stuffing box (or seal chamber) is accomplished by means of rings of packing forced between the two surfaces and held tightly in place by a packing gland. The leakage around the shaft is controlled by merely tightening or loosening the packing gland nuts (or bolts). The actual sealing surfaces consist of the axial rotating surface of the shaft or shaft sleeve and the stationary packing. Attempts to reduce or eliminate all leakage from a conventional packed stuffing box increase the compressive load of the packing

gland on the packing. The packing, being semiplastic, forms more closely to the shaft or shaft sleeve and tends to reduce the leakage. After a certain point, however, the leakage between the packing and the rotating shaft or shaft sleeve becomes inadequate to carry away the heat generated by the packing rubbing on the rotating surface, and the packing fails to function. This failure can result in burned packing, packing “blow out,” and severely damaged shaft or shaft sleeve surfaces. If the sealing surface is coated, this coating may be destroyed. Even before this condition is reached, the shaft or shaft sleeve may be severely worn and scored by the packing, so that it becomes impossible to pack the stuffing box satisfactorily.

These undesirable characteristics prohibit the use of packing as a sealing method if some leakage of the pumpage to the atmosphere is not acceptable. Packing is limited in its application pressure and temperature range (see Section 2.2.2), and it is usually not acceptable for any flammable or hazardous pumping services. To address these limitations, the mechanical seal was developed (see Section 2.2.3). The mechanical seal has found general acceptance in nearly all pumping applications. Packing is still used in certain low-pressure, low-temperature applications where leakage of the pumpage is not a problem and a history of satisfactory, economical service exists.

Mechanical seals are not always the solution to every sealing situation. Seals are still subject to failure, and their failure may be more rapid and abrupt than that of packing. If packing fails, the pump can many times be kept running by temporary adjustments until it is convenient to shut it down. If a mechanical seal fails, most often the pump must be shut down immediately. As both packed stuffing boxes and conventional mechanical face seals are subject to wear, both are subject to failure. Whether one or the other should be used depends on the specific application and the experience of the user. In some cases, both give good service and the choice becomes a matter of personal preference or cost. Table 2

TABLE 2 Comparison of packing and mechanical seals

| Advantages | Disadvantages |
|--|--|
| Packing | |
| 1. Lower initial cost | 1. Relatively high leakage |
| 2. Easily installed as rings and glands are split | 2. Requires regular maintenance |
| 3. Good reliability to medium pressures and shaft speeds | 3. Wear of shaft of shaft sleeve can be relatively high |
| 4. Can handle large axial movements (thermal expansion of stuffing box versus shaft) | 4. Power losses may be high |
| 5. Can be used in rotating or reciprocating applications | |
| 6. Leakage tends to increase gradually, giving warning of impending breakdown | |
| Mechanical seals | |
| 1. Very low leakage/no leakage | 1. Higher initial cost |
| 2. Require no maintenance | 2. Easily installed but may require some disassembly of pump (couplings and so on) |
| 3. Eliminate sleeve wear/shaft wear | |
| 4. Very good reliability | |
| 5. Can handle higher pressures and speeds | |
| 6. Easily applied to carcinogenic, toxic, flammable, or radioactive liquids | |
| 7. Low power loss | |

adds other comments and summarizes some advantages and disadvantages of packing and mechanical seals.

Principles and Construction of Mechanical Seals See Subsection 2.2.3.

Injection-Type Shaft Seals See Subsection 2.2.4.

BEARINGS

The function of bearings in centrifugal pumps is to keep the shaft or rotor in correct alignment with the stationary parts under the action of radial and transverse loads. Bearings that give radial positioning to the rotor are known as *radial or line bearings*, and those that locate the rotor axially are called *thrust bearings*. In most applications, the thrust bearings actually serve both as thrust and radial bearings.

Types of Bearings Used All types of bearings have been used in centrifugal pumps. Even the same basic design of pump is often made with two or more different bearings, required either by varying service conditions or by the preference of the purchaser. In most pumps, however, either rolling element or oil film (sleeve-type) bearings are used today.

In horizontal pumps with bearings on each end, the bearings are usually designated by their location as *inboard*, or drive end, and *outboard*, or non-drive end. Inboard (drive end) bearings are located between the casing and the coupling. Pumps with overhung impellers have both bearings on the same side of the casing so that the bearing nearest the impeller is called inboard and the one farthest away outboard. In a pump provided with bearings at both ends, the thrust bearing is usually placed at the outboard end and the line bearing at the inboard end.

The bearings are mounted in a housing that is usually supported by brackets attached or integral to the pump casing. The housing also serves the function of containing the lubricant necessary for proper operation of the bearing. Occasionally, the bearings of very large pumps are supported in housings that form the top of pedestals mounted on sole-plates or on the pump bedplate. These are called *pedestal bearings*.

Because of the heat generated by the bearing or the heat in the liquid being pumped, some means other than radiation to the surrounding air must occasionally be used to keep the bearing temperature within proper limits. If the bearings have a force-fed lubrication system, cooling is usually accomplished by circulating the oil through a separate water-to-oil or air-to-oil cooler. Otherwise, a jacket through which a cooling liquid is circulated is usually incorporated as part of the housing.

Pump bearings may be rigid or self-aligning. A self-aligning bearing will automatically adjust itself to a change in the angular position of the shaft. In babbitted or sleeve bearings, the name *self-aligning* is applied to bearings that have a spherical fit of the sleeve in the housing. In rolling element bearings, the name is applied to bearings, the outer race of which is spherically ground or the housing of which provides a spherical fit.

Although double-suction pumps are theoretically in hydraulic balance, this balance is rarely realized in practice, and so even these pumps are provided with thrust bearings. A centrifugal pump, being a product of the foundry, is subject to minor irregularities that may cause differences in the eddy currents set up on the two sides of the impeller. As this disturbance can create an axial hydraulic thrust, some form of thrust bearing that is capable of taking a thrust in either direction is necessary to maintain the rotor in its proper position.

The thrust capacity of the bearing of a double-suction pump is usually far in excess of the probable imbalance caused by irregularities. This provision is made because (1) unequal wear of the rings and other parts may cause an imbalance and (2) the flow of the liquid into the two suction eyes may be unequal and cause an imbalance because of an improper suction-piping arrangement.

Rolling Element Bearings The most common rolling element bearings used on centrifugal pumps are the various types of ball bearings. Roller bearings are used less often, although the spherical roller bearing (see Figure 86) is used frequently for large shaft

FIGURE 86 Self-aligning spherical roller bearing (SKF USA, Inc.)

sizes, for which there is a limited choice of ball bearings. As most roller bearings are suitable only for radial loads, their use on centrifugal pumps tends to be limited to applications in which they are not required to carry a combined radial and thrust load.

Ball Bearings As the coefficient of rolling friction is less than that of sliding friction, one must not consider a ball bearing in the same light as a sleeve bearing. In the former, the load is carried on a point contact of the ball with the race, but the point of contact does not rub or slide over the race and no appreciable heat is generated. Furthermore, the point of contact is constantly changing as the ball rolls in the race, and the operation is practically frictionless. In the sleeve bearing, a constant rubbing of one surface over another occurs, and the friction must be reduced by the use of a lubricant.

Ball bearings that operate at an absolutely constant speed theoretically require no lubricant. No speed can be called absolutely constant, however, for the conditions affecting the speed always vary slightly. For instance, a motor with a full-load speed rated at 3,510 rpm might vary in speed over the course of a minute from 3,505 to 3,515 rpm. Each variation in speed causes the balls in a ball bearing to lag or lead the race because of their inertia. Consequently, a very slight, almost immeasurable sliding action takes place. Another limiting condition is that the hardest of metals suffers minute deformations on carrying loads, thus upsetting perfect point contacts and adding another slight sliding action. For these reasons, ball bearings must be given some lubrication.

Ball thrust bearings are built to carry heavy loads by pure rolling motion on an angular contact. As a thrust load is axial, it is equally distributed to all the balls around the race, and the individual load on each ball is only a small fraction of the total thrust load. In such bearings, it is essential that the balls be equally spaced, and for this purpose, a retaining cage is used between the balls and between the inner and outer races. This cage carries no load, but the contact between it and the ball produces sliding friction that requires lubrication.

Types and Applications Pump designers have a wide variety of rolling element bearings and arrangements to choose from. Ball bearings with their high-speed capabilities and low friction make them ideal for small and medium-size pumps, while roller bearings are more common in larger, slower speed pumps where a heavy capacity is required. Depending upon the specific bearing type, optional characteristics such as seals, shields, various cage materials and designs, and special internal clearances and preloads are available. Although several might be dimensionally acceptable, it is best for users to adhere to manufacturer recommendations to ensure optimum reliability.

The most common ball bearings used in centrifugal pumps are 1) single-row, deep-groove, 2) single-row, angular contact, and 3) double-row, angular contact ball bearings.

Sealed ball bearings are used in special applications such as vertical in-line pumps. Sealed prelubricated bearings require special attention if the unit in which they are

FIGURE 87 Self-aligning ball bearing (SKF USA, Inc.)

FIGURE 88 Single-row, deep-groove ball bearing (SKF USA, Inc.)

installed is not operated for long periods of time (such as stand-by units or units kept in stock or storage). The shaft should be rotated occasionally (see specific instruction manual directions) to agitate the lubricant and maintain a film coating on the bearing elements.

Self-aligning ball bearings (see Figure 87) are sometimes used for heavy loads, high speeds, long-bearing spans (large deflection angles at the bearings) and no axial thrust requirements. This bearing design acts as a pivot that compensates for misalignment and shaft deflection. For large shafts, the self-aligning spherical roller bearing (refer to Figure 86) is used instead of the self-aligning ball bearing, and it can carry both radial loads and axial thrust loads.

The single-row, deep-groove ball bearing (see Figure 88), sometimes referred to as a Conrad-type bearing, is the most commonly used bearing in centrifugal pumps, except for the larger size pumps. The Conrad-type design is recommended for use in centrifugal pumps because it can support either radial, axial, or a combination of radial and axial loads. This makes it ideal for the radial bearing in end-suction centrifugal pumps or as both the radial and thrust bearings in small pumps. The bearing design requires a careful alignment between the shaft and the housing. It is often used with seals or shields in grease-lubricated applications to help exclude dirt and retain lubricants within the bearing.

Angular contact ball bearings are commonly used in centrifugal pump applications to support axial loads or a combination of both axial and radial loads. Their axial stiffness and small operating clearances provide precise position accuracy for the shaft. Angular contact bearings are manufactured in a single-row design (see Figure 89), typically with a 40° contact angle, and also as a double-row bearing (see Figure 90), most commonly with a 30° contact angle.

Single-row, angular contact ball bearings support axial loads in only one direction when used singly. To support reversing axial loads or combined loads, single-row bearings must be mounted in a back-to-back or face-to-face arrangement where the contact angles oppose each other. Owing to its more rigid design, the back-to-back arrangement is generally recommended for centrifugal pumps, while the face-to-face arrangement is common when a slight misalignment is expected. When required to support heavy axial loads, single-row, angular contact ball bearings can be mounted in tandem where their contact angles are in the same direction. This arrangement must still be opposed with a third bearing in a back-to-back or face-to-face arrangement with the tandem pair when radial or reversing thrust loads must also be supported (see Figure 91). Depending upon the operating conditions of the pump, single-row, angular contact ball bearings typically operate with either a small clearance or a light preload.

Some applications exist where a high axial load occurs predominantly in one direction, but the thrust bearing must be capable of carrying occasional smaller axial loads in the

FIGURE 89 Single-row, angular contact bearing (SKF USA, Inc.)

FIGURE 90 Double-row, angular-contact bearing (SKF USA, Inc.)

FIGURE 91 Paired bearing arrangements (SKF USA, Inc.)

reversing direction. When this occurs, a typical back-to-back angular contact bearing arrangement can result in one bearing becoming nearly completely unloaded. In the most severe cases of axial unloading of angular contact bearings, skidding of the unloaded balls within the bearing races can occur. This skidding can result in bearing heating and subsequent damage, even failure, with time. To avoid ball skidding under light load or no-load conditions, standard angular contact bearing sets can be arranged for a light preload that will result in a sufficient load on the dynamically unloaded bearing to prevent skidding. Another alternative is to install a matched set of two angular contact bearings with different contact angles (see Figure 92). By utilizing an angular contact bearing with a lower contact angle (say 15 degrees instead of the normal 40 degrees), the unloaded bearing will have a lower requirement for an axial load and be more resistant to ball skidding. This means the bearing will run at a lower temperature.

The double-row, angular contact ball bearing (see Figure 93) is similar in design to a back-to-back pair of single-row, angular contact ball bearings, but in a narrower width package. Its ease of mounting, along with its low-friction operation, high-speed capability, and seal or shield availability, make it an ideal bearing for light- to medium-duty end suction centrifugal pumps and submersible pumps.

Lubrication of Antifriction Bearing In the layout of a line of centrifugal pumps, the choice of the lubricant for the pump bearings is dictated by application requirements, by cost considerations, and sometimes by the preferences of a group of purchasers committed to the major portion of the output of that line. For example, in vertical wet-pit condenser circulating pumps, water is the lubricant of choice, in preference to grease or oil. If oil or grease is used in such pumps and the lubricant leaks into the pumping system, the condenser operation might be seriously affected because the tubes would become coated with the lubricant.

FIGURE 92 Angular contact bearings with different contact angles (SKA USA, Inc.)

FIGURE 93 A double-row, angular-contact ball thrust bearing that is grease-lubricated and water-cooled

Most centrifugal pumps for refinery services are supplied with oil-lubricated bearings because of the insistence of refinery engineers on this feature. In the marine field, on the other hand, the preference lies with grease-lubricated bearings. For high pump operating speeds (5,000 rpm and above), oil lubrication is found to be the most satisfactory. For highly competitive lines of small pumps, the main consideration is cost, and so the most economical lubricant is chosen, depending upon the type of bearing used.

Ball bearings used in small centrifugal pumps are usually grease-lubricated, although some services use oil lubrication. In grease-lubricated bearings, the grease packed into the bearing is thrown out by the rotation of the balls, creating a slight suction at the inner race. (Even if the grade of grease is relatively light, it is still a semisolid and flows slowly. As heat is generated in the bearing, however, the flow of the grease is accelerated until the grease is thrown out at the outer race by the rotation.) As the expelled grease is cooled by contact with the housing and thus is attracted to the inner race, a continuous circulation of grease lubricates and cools the bearing. This method of lubrication requires a minimum amount of attention and has proved itself very satisfactory. A vertically mounted thrust bearing arranged for grease lubrication is shown in Figure 94.

A bearing fully packed with grease prevents proper grease circulation in itself and its housing. Therefore, as a general rule, it is recommended that only one-third of the void spaces in the housing be filled. An excess amount of grease will cause the bearing to heat up, and grease will flow out of the seals to relieve the situation. Unless the excess grease can escape through the seal or through the relief cock that is used on many large units, the bearing will probably fail early.

In oil-lubricated ball bearings, a suitable oil level must be maintained in the housing. This level should be at about the center of the lowermost ball of a stationary bearing. It can be achieved by a dam and an oil slinger to maintain the level behind the dam and thereby increase the leeway in the amount of oil the operator must keep in the housing. Oil rings are sometimes used to supply oil to the bearings from the bearing housing reservoir (see Figure 95). In other designs, a constant-level oiler is used (see Figure 96).

Because of the advantages of interchangeability, some pump lines are built with bearing housings that can be adapted to either oil or grease lubrication with minimum modifications (see Figure 97).

FIGURE 94 Vertically mounted thrust bearing arranged for grease lubrication (SKF USA, Inc.)

FIGURE 95 A ball bearing pump with oil rings

COUPLINGS

Centrifugal pumps are connected to their drivers through couplings of one sort or another, except for close-coupled units, in which the impeller is mounted on an extension of the shaft of the driver.

Because couplings can be used with both centrifugal and positive displacement pumps, they are discussed separately in Section 6.3.

BEDPLATE AND OTHER PUMP SUPPORTS

For very obvious reasons, it is desirable that pumps and their drivers be removable from their mountings. Consequently, they are usually bolted and doweled to machined surfaces that in turn are firmly connected to a foundation. To simplify the installation of horizontal-shaft units, these machined surfaces are usually part of a common bedplate on which either the pump or the pump and its driver have been prealigned.

FIGURE 96 A constant-level oiler

FIGURE 97 Ball bearings arranged (left) with oil rings in the housing and (right) for grease lubrication

Bedplates The primary function of a pump bedplate is to furnish mounting surfaces for the pump feet that can be rigidly attached to the foundation. Mounting surfaces are also necessary for the feet of the pump driver or drivers and for the feet of any independently mounted power transmission device. Although such surfaces could be provided by separate bedplates or by individually planned surfaces, it would be necessary to align these separate surfaces and fasten them to the foundation with the utmost care. Usually, this method requires in-place mounting in the field as well as drilling and tapping for the bolts after all the parts have been aligned. To minimize such field work, coupled horizontal-shaft pumps are usually purchased with a continuous base extending under the pump and its driver. Ordinarily, both these units are mounted and aligned at the place of manufacture.

Although such bases are designed to be quite rigid, they deflect if improperly supported. It is therefore necessary to support them on a foundation that can supply the required rigidity. Furthermore, as the base can be sprung out of shape by improper handling during transit, it is imperative that the alignment be carefully rechecked during erection and prior to starting the unit.

FIGURE 98 Horizontal shaft overhung pump and driver on a structural steel bedplate with a raised edge around the base and a tapped drainage connection (Flowserve Corporation)

FIGURE 99 Horizontal shaft centrifugal pump and internal combustion engine mounted on a structural steel bedplate (Flowserve Corporation)

As the unit size increases, so does the size, weight, and cost of the base required. The cost of a prealigned base for most large units exceeds the cost of the field work necessary to align individual bedplates or soleplates and to mount the component parts. Such bases are therefore used only if appearances require them or if their function as a drip collector justifies the additional cost. Even in fairly small units, the height at which the feet of the pump and the other elements are located may differ considerably. A more rigid and nice-looking installation can frequently be obtained by using individual bases or soleplates and building up the foundation to various heights under the separate portions of equipment.

Baseplates are usually provided with a raised edge or raised lip around the base to prevent dripping or draining onto the floor (see Figure 98). The base itself is sloped toward

FIGURE 100 Horizontal shaft centrifugal pump and driver on a structural steel bedplate made of a simple channel shape (Flowserve Corporation)

FIGURE 101 Single-stage double-suction pump with centerline support (Flowserve Corporation)

one end to collect the drainage for further disposal. A drain pocket is provided near the bottom of the slope, sometimes with a mesh screen. A tapped connection in the pocket permits piping the drainage to a convenient point.

Bedplates are usually fabricated from steel plate and structural steel shapes (see Figures 99 and 100). Even though most of these fabrications have a drain capability, because of the popular use of mechanical seals and the containment of stuffing box leakage for pumps that continue to use shaft packing (leakage is usually collected in the bearing bracket and piped to a common collecting point), the bedplate surfaces actually are seldom used to collect leakage from the pumping equipment during operation. Bedplate drain surfaces are usually employed to contain the leakage of pumpage and other liquids during pump maintenance and removal or in the event of a seal or packing failure.

Soleplates Soleplates are cast-iron or steel pads located under the feet of the pump or its driver and are embedded in the foundation. The pump or its driver is doweled and bolted to them. Soleplates are customarily used for vertical dry-pit pumps and also for some of the larger horizontal units to save the cost of the large bedplates otherwise required.

Centerline Support For operation at high temperatures, the pump casing must be supported as near to its horizontal centerline as possible in order to prevent excessive strains caused by temperature differences. Such strains might seriously disturb the alignment of the unit and eventually damage it. Centerline construction is usually employed in boiler-feed, refinery, and hot-water circulating pumps (see Figure 101). The exact temperature at which centerline support construction becomes mandatory varies from 250 to 350°F (121 to 177°C).

Horizontal Units Using Flexible Pipe Connections The previous discussion of bedplates and supports for horizontal-shaft units assumed their application would be to pumps with piping setups that do not impose hydraulic thrusts on the pumps. If flexible pipe connections or expansion joints are desirable in the suction or discharge piping of a pump (or in both), the pump manufacturer should be so advised for several reasons. First, the pump casing will be required to withstand various stresses caused by the resultant hydraulic thrust load. Although this is rarely a limiting or dangerous factor, it is best that the manufacturer have the opportunity to check the strength of the pump casing. Second, the resulting hydraulic thrust has to be transmitted from the pump casing through the casing feet to the bedplate or soleplate and then to the foundation. Usually, horizontal-shaft pumps are merely bolted to their bases or soleplates, and so any tendency to displacement is resisted only by the frictional grip of the casing feet on the base and by relatively small dowels. If flexible pipe joints are used, this attachment may not be sufficient to withstand the hydraulic thrust. If high hydraulic thrust loads are to be encountered, therefore the pump feet must be keyed to the base or supports. Similarly, the

bedplate or supporting soleplates must be of a design that will permit transmission of the load to the foundation. Each of these design elements must be checked to confirm their capability to withstand hydraulic thrust loads from flexible pipe connections. Preferably expansion joints will be restrained to avoid transmitting loads to the pump nozzles.

VERTICAL PUMPS

Vertical-shaft pumps fall into two classifications: dry-pit and wet-pit. Dry-pit pumps are surrounded by air, and the wet-pit types are either fully or partially submerged in the liquid handled.

Vertical Dry-Pit Pumps Dry-pit pumps with external bearings include most small, medium, and large vertical sewage pumps, most medium and large drainage and irrigation pumps for medium and high heads, many large condenser circulating and water supply pumps, and many marine pumps. Sometimes the vertical design is preferred (especially for marine pumps) because it saves floor space. At other times, it is desirable to mount a pump at a low elevation because of suction conditions, and it is then also preferable or necessary to have the pump driver at a high elevation. The vertical pump is normally used for large capacity applications because it is more economical than the horizontal type, all factors considered.

Many vertical dry-pit pumps are basically horizontal designs with minor modifications (usually in the bearings) to adapt them for vertical-shaft drive. This is not true of small- and medium-sized sewage pumps, however. In these units, a purely vertical design is the most popular. Most of these sewage pumps have elbow suction nozzles (see Figures 102 through 104) because their suction supply is usually taken from a wet well adjacent to the

FIGURE 102 Section of a vertical sewage pump with end-suction (elbow) and side discharge (Flowserve Corporation)

FIGURE 103 An installed vertical sewage pump similar to that shown in Figure 102 (Flowserve Corporation)

FIGURE 104 Vertical sewage pump with a direct-mounted motor (Flowserve Corporation)

pit in which the pump is installed. The suction elbow usually contains a handhole with a removable cover to provide easy access to the impeller.

To dismantle one of these pumps, the stuffing box head must be unbolted from the casing after the intermediate shaft or the motor and motor stand have been removed. The rotor assembly is drawn out upward, complete with the stuffing box head, the bearing

FIGURE 105 Vertical bottom-suction volute pumps installed in a sewage pumping station (Flowserve Corporation)

housing, and the like. This rotor assembly can then be completely dismantled at a convenient location.

Vertical-shaft installations of single-suction pumps with a suction elbow are commonly furnished with either a pedestal or a base elbow (refer to Figure 102), both of which can be bolted to soleplates or even grouted in. The grouting arrangement is not desirable unless there is full assurance that the pedestal or elbow will never be disturbed or that the grouted space is reasonably regular and the grout will separate from the pump without excessive difficulty.

Vertical single-suction pumps with bottom suction are commonly used for larger sewage, water supply, or condenser circulating applications. Such pumps are provided with wing feet that are bolted to soleplates grouted in concrete pedestals or piers (see Figure 105). Sometimes the wing feet may be grouted right in the pedestals. These must be suitably arranged to provide proper access to any handholes in the pump and to allow clearance for the elbow suction nozzles if these are used.

If a vertical pump is applied to a condensate service or some other service for which the eye of the impeller must be vented to prevent vapor binding, a pump with a bottom single-inlet impeller is not desirable because it does not permit effective venting. Neither does a vertical pump employing a double-suction impeller (see Figure 106). The most suitable design for such applications incorporates a top single-inlet impeller (see Figure 107).

If the driver of a vertical dry-pit pump can be located immediately above the pump, it is often supported on the pump itself (refer to Figure 104). The shafts of the pump and driver may be connected by a flexible coupling, which requires that each have its own thrust bearing. If the pump shaft is rigidly coupled to the driver shaft or is an extension of the driver shaft, a common thrust bearing is used, normally in the driver.

Although the driving motors are frequently mounted on top of the pump casing, one important reason for the use of the vertical shaft design is the possibility of locating the motors at an elevation sufficiently above the pumps to prevent the accidental flooding of the motors. The pump and its driver may be separated by an appreciable length of shafting, which may require steady bearings between the two units. Subsection 6.3.1 discusses the construction and arrangement of the shafting used to connect vertical pumps to drivers located some distance above the pump elevation.

Bearings for vertical dry-pit pumps and for intermediate guide bearings are usually antifriction grease-lubricated types to simplify the problem of retaining a lubricant in a housing with a shaft projecting vertically through it. Larger units, for which antifriction bearings are not available or desirable, use self-oiling, babbitt steady bearings with spiral

FIGURE 106 A vertical double-suction volute pump with a direct-mounted motor (Flowserve Corporation)

FIGURE 107 A section of a vertical pump with a top-suction inlet impeller (Flowserve Corporation)

FIGURE 108 A self-oiling, babbitt steady bearing for large vertical shafting (Flowserve Corporation)

FIGURE 109 A section of a large, vertical, bottom-suction volute pump with a single sleeve bearing (Flowserve Corporation)

oil grooves (see Figures 108 and 109). Figure 109 illustrates a vertical dry-pit pump design with a single-sleeve line bearing. The pump is connected by a rigid coupling to its motor (not shown), which is provided with a line and a thrust bearing.

Vertical dry-pit centrifugal pumps are structurally similar to horizontal-shaft pumps. It is to be noted, however, that many of the large, vertical, single-stage, single-suction (usually bottom) volute pumps that are preferred for large storm water pumpage, drainage, irrigation, sewage, and water supply projects have no comparable counterpart among horizontal-shaft units. The basic U-section casing of these pumps, which is structurally weak, often requires the use of heavy ribbing to provide sufficient rigidity. In the comparable water turbine practice, a set of vanes (called a *speed ring*) is employed between the casing and the runner to act

as a strut. Although the speed ring does not adversely affect the operation of a water turbine, it would function basically as a diffuser in a pump because of the inherent hydraulic limitations of that construction. Some high-head pumps of this type have been made in the twin-volute design. The wall separating the two volutes acts as a strengthening rib for the casing, thus making it easier to design a casting strong enough for the pressure involved.

Bases and Supports for Vertical Pumping Equipment Vertical-shaft pumps, like horizontal-shaft units, must be firmly supported. Depending upon the installation, the unit can be supported at one or several elevations. Vertical units are seldom supported from walls, but even that type of support is sometimes encountered.

Occasionally, a nominal horizontal-shaft pump design is arranged with a vertical shaft and a wall used as the supporting foundation. Regular horizontal-shaft units can be used for this purpose without modification, except that the bedplate is attached to a wall. Careful attention must be given to the arrangement of the pump bearings to prevent the escape of the lubricant. Installations of double-suction, single-stage pumps with the shaft in the vertical position are relatively rare, except in some marine or navy applications. Hence, manufacturers have few standard pumps of this kind arranged so that a portion of the casing forms the support (to be mounted on soleplates). Figure 106 shows such a pump, which also has a casing extension to support the driving motor.

Vertical Wet-Pit Pumps Vertical pumps intended for submerged operations are manufactured in a great number of designs, depending mainly upon the service for which they are intended. Small pumps of this type are often referred to as *sump pumps*. Wet-pit centrifugal pumps can be classified in the following manner:

- Vertical turbine pumps
- Propeller or modified propeller pumps
- Volute pumps

Vertical Turbine Pumps Vertical turbine pumps were originally developed for pumping water from wells and have been called *deep-well pumps*, *turbine well pumps*, and *bore-hole pumps*. As their application to other fields has increased, the name *vertical turbine pumps* has been generally adopted by manufacturers. This is not too specific a designation because the term *turbine pump* has been applied in the past to any pump employing a diffuser. There is now a tendency to designate pumps using diffusion vanes as *diffuser pumps* to distinguish them from *volute pumps*. As that designation becomes more universal, applying the term *vertical turbine pumps* to the construction formerly called *turbine well pumps* will become more specific.

The largest fields of application for the vertical turbine pump are pumping from wells for irrigation and other agricultural purposes, for a municipal water supply, and for industrial water supplies, as well as for processing, circulating, refrigerating, and air conditioning. This type of pump has also been utilized for brine pumping, mine dewatering, oil field repressuring, and other purposes.

These pumps have been made for capacities as low as 10 or 15 gpm (2 or 3 m³/h) and as high as 25,000 gpm (5700 m³/h) or more and for heads up to 1,000 feet (300 m). Most applications naturally involve the smaller capacities. The capacity of the pumps used for bored wells is naturally limited by the size of the well as well as by the rate at which water can be drawn without lowering its level to a point of insufficient pump submergence.

Vertical turbine pumps should be designed with a shaft that can be readily raised or lowered from the top to permit proper positioning of the impeller in the bowl. An adequate thrust bearing is also necessary to support the vertical shafting, the impeller, and the hydraulic thrust developed when the pump is in service. As the driving mechanism must also have a thrust bearing to support its vertical shaft, it is usually provided with one large enough to carry the pump parts as well. For these two reasons, the hollow-shaft motor or gear is most commonly used for vertical turbine pump drives. In addition, these pumps are sometimes made with their own thrust bearings to allow for a belt drive or for a drive through a flexible coupling by a solid-shaft motor, gear, or turbine. Dual-driven pumps usually employ an angle gear with a vertical motor mounted on its top.

FIGURE 110 A vertical turbine pump design with enclosed impellers and: a) enclosed line shafting and b) open-line shafting (Flowsolve Corporation)

The design of vertical pumps illustrates how a centrifugal pump can be specialized to meet a specific application. Figure 110 illustrates a turbine design with closed impellers and enclosed-line shafting and another turbine design with closed impellers and open-line shafting.

The bowl assembly, or section, consists of the suction case (also called *suction head* or *inlet vane*), the impeller or impellers, the discharge bowl, the intermediate bowl or bowls (if more than one stage is involved), the discharge case, the various bearings, the shaft, and the miscellaneous parts, such as keys, impeller-locking devices, and the like. The column pipe assembly consists of the column pipe, the shafting above the bowl assembly, the shaft bearings, and the cover pipe or bearing retainers. The pump is suspended from the driving head, which consists of the discharge elbow (for above ground discharge), the motor or driver and support, and either the stuffing box (in an open-shaft construction) or the assembly for providing tension on the cover pipe and introducing a lubricant into it. Below ground discharge is taken from a tee in the column pipe, and the driving head functions principally as a stand for the driver and a support for the column pipe.

Liquid in a vertical turbine pump is guided into the impeller by the suction case or head. This may be a tapered section for the attachment of a conical strainer or suction pipe, or it may be a bell mouth.

Semiopen and enclosed impellers are both commonly used. For proper clearances in the various stages, the semiopen impeller requires more care in assembly on the impeller shaft and more accurate field adjustments of the vertical shaft position in order to obtain the best efficiency. Enclosed impellers are favored over semiopen ones because wear on the latter reduces capacity, which cannot be restored unless new impellers are installed. Normal wear on enclosed impellers does not affect impeller vanes, and worn clearances may be restored by replacing wearing rings. The thrust produced by semiopen impellers may be as much as 150 percent of that by enclosed impellers.

Occasionally, in power plants, the maximum water level that can be carried in the condenser's hot well will not give adequate NPSH for a conventional horizontal condensate pump mounted on the basement floor, especially if the unit has been installed in a space originally allotted for a smaller pump. Building a pit for a conventional horizontal condensate pump or a vertical dry-pit pump that will provide sufficient submergence involves considerable expense. Pumps of the design shown in Figure 111 have become quite popular in such applications. This is basically a vertical turbine pump mounted in a tank (often called a can) that is sunk into the floor. The length of the pump has to be such that sufficient NPSH will be available for the first-stage impeller design, and the diameter and length of the tank have

FIGURE 111 Vertical turbine can pump for condensate service (Flowserve Corporation)

FIGURE 112 Vertical propeller pump installed (Flowsolve Corporation)

to allow for proper flow through the space between the pump and tank and then for a turn and flow into the bell mouth. Installing this design in an existing plant is naturally much less expensive than making a pit because the size of the hole necessary to install the tank is much smaller. The same basic design has also been applied to pumps handling volatile liquids that are mounted on the operating floor and not provided with sufficient NPSH.

Propeller Pumps Originally, the term *vertical propeller pump* was applied to vertical wet-pit diffuser or turbine pumps with a propeller or axial-flow impellers, usually for installation in an open sump with a relatively short setting (see Figures 112 and 113). Operating heads exceeding the capacity of a single-stage axial-flow impeller might call for a pump of two or more stages or a single-stage pump with a lower specific speed and a mixed-flow impeller. High enough operating heads might demand a pump with mixed-flow impellers and two or more stages. For lack of a more suitable name, such high-head designs have usually been classified as propeller pumps also.

Although vertical turbine pumps and vertical modified propeller pumps are basically the same mechanically and could even be of the same specific speed hydraulically, a basic turbine pump design is suitable for a large number of stages. A modified propeller pump design, however, is basically intended for a maximum of two or three stages.

Most wet-pit drainage, low-head irrigation, and storm water installations employ conventional propeller or modified propeller pumps. These pumps have also been used for condenser circulating services, but a specialized design dominates this field. As large power plants are usually located in heavily populated areas, they frequently have to use badly contaminated water (both fresh and salt) as a cooling medium. Such water quickly short-

FIGURE 113 Vertical propeller pump with above ground discharge (Flowserve Corporation)

FIGURE 114 Vertical pull-out design allows the rotating element and critical non-rotating wear components to be removed for inspection and replacement without removing the complete pump (Flowserve Corporation)

ens the life of fabricated steel. Cast iron, bronze, or an even more corrosion-resistant cast metal must therefore be used for the column pipe assembly. This requirement means a very heavy pump if large capacities are involved. To avoid the necessity of lifting this large mass for maintenance of the rotating parts, some designs (one of which is illustrated in Figure 114) are built so that the impeller, diffuser, and shaft assembly can be removed from the top without disturbing the column pipe assembly. These designs are commonly designated as *pullout* designs.

Like vertical turbine pumps, propeller and modified propeller pumps have been made with both open- and enclosed-line shafting. Except for condenser circulating services, enclosed shafting, using oil as a lubricant but with a grease-lubricated tail bearing below the impeller, seems to be favored. Some pumps handling condenser

circulating water use enclosed shafting but with water (often from another source) as the lubricant, thus eliminating any possibility of oil getting into the circulating water and coating the condenser tubes.

Propeller pumps have open propellers. Modified propeller pumps with mixed-flow impellers are made with both open and closed impellers.

Volute Pumps A variety of wet-pit pumps are available. The liquid pumped, be it clean water, sewage, abrasive liquids or slurries, dictates whether a semiopen or an enclosed impeller will be used, whether the shafting will be open or closed to the liquid pumped, and whether the bearings will be submerged or located above the liquid.

Figure 115 illustrates a single-volute pump with a single-suction enclosed nonclog impeller, no pump-out vanes or wearing-ring joints on the back side of the impeller, and enclosed shafting. The pump is designed to be suspended from an upper floor by means of a drop pipe and for pumping sewage or other solid-laden liquids. To seal against leakage along the shaft at the point where it passes through the casing, a seal chamber or a stuffing box is provided. The design of a stuffing box can be either like the one shown in Figure 116, which uses rings of packing and a spring-loaded gland, or the one shown in Figure 117, which uses U-cup packing requiring no gland. The pump shown in Figure 115 uses two sleeve bearings above the impeller. The bottom bearing is grease-lubricated, and a seal is provided to prevent grease leakage as well as to keep out any grit. The upper bearing connects the shaft cover pipe to the pump-bearing bracket and the upper end of the cover pipe to the floorplate. This bearing is gravity-feed oil-lubricated. If intermediate bearings are required, they are also supported by the cover pipe and are oil-lubricated. The pump thrust is carried by the motor, which can be either a hollow-shaft or a solid-shaft construction. The latter type requires the use of a rigid coupling between the pump and motor shafts.

In most applications, these volute-type pumps have been replaced with vertical wet-pit pumps with the stuffing box/seal chamber in the discharge head (see Section 9.2, Figure 4b).

A design that uses open shafting and no seal chamber or stuffing box at the pump casing, incorporating its own thrust bearing, is shown in Figure 118. The impeller shown in Figure 118 is of the vortex type (sometimes called a *recessed impeller*, as shown in Figure 119), which is suitable for pumping heavy concentrations of solid material (such as sludges or slurries) or in certain food-processing applications, but other types of impellers can be substituted. Pumped liquid leakage from the casing is relieved back to the suction through holes in the support pipe. The seal chamber or stuffing box at the driver floor elevation is used only when gas tight construction is desired. The lower and any intermediate sleeve bearings are grease-lubricated as shown, but gravity-feed oil lubrication is also available in other designs. The upper antifriction thrust bearing is grease-lubricated. A solid shaft motor and a flexible shaft are used.

Figure 120 illustrates what is called a *cantilever-shaft pump*, which has the unique feature of having no bearings below the liquid surface. The shaft is exposed to the liquid pumped. External antifriction grease-lubricated bearings are provided above the floor and are properly spaced to support the rigid shaft. They carry both the thrust and the radial load. A flexible coupling is used between the pump and the solid-shaft motor. The stuffing box at the floorplate may be eliminated if holes are provided in the drop pipe to maintain the liquid level in the pipe even with the sump liquid level. Either semiopen or enclosed impellers may be used.

An interesting design of the wet-pit pump is shown in Figure 121. It uses a single-stage, double-suction impeller in a twin-volute casing. Because the axial thrust is balanced, the thrust bearing need carry only the weight of the rotating element. The pump requires no stuffing box or mechanical seal. The shaft is entirely enclosed, and the bearings are externally lubricated, either with oil or with water. The lower bearing receives its lubrication from an external pipe connection.

The term sump pump ordinarily conveys the idea of a vertical wet-pit pump that is suspended from a floorplate or sump cover. It could be supported by a foot on the bottom of a well, be motor-driven and automatically controlled by a float switch, and be used to remove drainage collected in a sump. The term does not indicate a specific construction, for both diffuser and volute designs are used. These may be single-stage or multistage and have open or closed impellers of a wide range of specific speeds.

FIGURE 115 A section of a vertical wet-pit, nonclogging pump (Flowsolve Corporation)

For small capacities driven by fractional-horsepower motors, *cellar drainers* can be used. These are small and usually single-stage volute pumps with single-suction impellers (either top or bottom suction) supported by a foot on the casing. The motor is supported well above the impeller by some form of column enclosing the shaft. These drainers are made as complete units, including float, float switch, motor, and strainers (see Figure 122).

The larger sump pumps are usually standardized but obtainable in any length, with covers of various sizes (on which a float switch may be mounted) and the like. Duplex

FIGURE 116 A typical stuffing box arrangement

FIGURE 117 A stuffing box arrangement with U-cup packing (Flowserve Corporation)

units, that is, two pumps on a common sump cover (sometimes with a hole for access to the sump), are often used (see Figure 123). Such units may operate their pumps in a fixed order, or a mechanical or electric alternator may be used to equalize their operation.

The Application of Vertical Wet-Pit Pumps Like all pumps, the vertical wet-pit pump has advantages and disadvantages. One advantage is that installation does not require a separate dry pit to collect the pumped liquid. If the impeller (first-stage impeller in multistage pumps) is submerged, no priming problem exists and the pump can be automatically controlled without fear of its ever running dry. Moreover, the available NPSH is greater (except in closed tanks) and often permits a higher rotative speed for the same service conditions. A second advantage is that the motor or driver can be located at any desired height above any flood level.

It has the following mechanical disadvantages: (1) the possibility of freezing when idle, (2) the possibility of damage by floating objects if the unit is installed in an open ditch or similar installation, (3) the inconvenience of lifting out and dismantling for inspection and repairs, no matter how small, and (4) the pump bearings have a relative short life unless the water and bearing design are ideal. In summary, the vertical wet-pit pump is the best pump available for some applications. It's not ideal but can be the most economical for certain installations, a poor choice for some, and the least desirable for still others.

FIGURE 118 A vertical wet-pit volute pump with open shafting, no stuffing box, and its own thrust bearing (Aurora Pump)

FIGURE 119 The principle operation of the vortex pump in Figure 118 (Aurora Pump)

Axial Thrust in Vertical Pumps with Single Suction Impellers The subject of axial thrust in horizontal pumps has already been discussed in this section. When pumps are installed in a vertical position, additional factors need be taken into account when determining the amount and direction of the thrust to be absorbed in the thrust bearings.

The first and most significant of these factors is the weight of the rotating parts, which is a constant downward force for any given pump, completely independent of the pump operating capacity or total head. Since in most cases the single-suction impellers of vertical pumps are mounted with the suction eye facing downward, the normal hydraulic axial thrust is exerted downward and the weight of the rotating parts is additive to this axial thrust.

The second factor involves the dynamic force (or change in momentum) caused by the change in the direction of flow, from vertical to either horizontal or partly horizontal, as the pumped liquid flows through the impeller. This force acts upward and balances a small portion of the hydraulic downthrust and of the rotor weight. The magnitude of this force for water having a specific weight (force) of 62.34 lb/ft^3 (9.79 kN/m^3) is

FIGURE 120 Vertical wet-pit cantilever-type volute pump: (1) impeller nut, (2) open impeller, (3) closed impeller, (4) open casing, (5) closed casing, (6) casing wearing ring, (7) casing gasket, (8) discharge flange gasket, (9) back cover, (10) packing or mechanical seal, (11) packing or seal gland, (12) radial bearing, (13) shaft, (14) supporting pipe, (15) separate stuffing box, (16) sump cover, (17) discharge pipe, (18) upper motor pedestal, (19) lower motor pedestal, (20) lower thrust bearing cover, (21) thrust bearing, (22) upper thrust bearing cover, (23) coupling, (24) motor, (25) bearing locknut and washer (Laurence Pump)

FIGURE 122 A cellar-drainer sump pump (Sta-Rite Products)

in USCS units

$$F_u = \frac{KV_e^2 A_e}{2g(2.31)}$$

in SI units

$$F_u = \frac{KV_e^2 A_e}{2g(1.02)}$$

where F_u = upthrust, lb (N)
 K = constant related to the impeller type
 V_e = velocity in the impeller eye ft/s (m/s)

FIGURE 123 A duplex sump pump (Economy Pump)

$A_e = \text{net eye area, in}^2(\text{cm}^2)$
 $g = 32.2 \text{ ft/s}^2(9.81 \text{ m/s}^2)$

The constant K is 1.0 for a fully radial-flow impeller, less than 1.0 for a mixed-flow impeller, and essentially zero for a fully axial-flow impeller.

Under normal operating conditions, the upward thrust caused by the change of momentum is hardly significant in comparison with the downward thrust caused by the unbalanced pressures acting on the single-suction impeller. Consider the example of an impeller with the following characteristics:

| | |
|---------------------|---|
| Capacity | 2,500 gpm (568 m ³ /h) |
| Total head | 231 ft (70.4 m) |
| Net pressure | 100 lb/in ² (6.89 bar) |
| Unbalanced eye area | 40 in ² (258 cm ²) |

If we neglect the effect of the pressure distribution on the shrouds of the impeller, the downward thrust is

in USCS units $100 \times 40 = 4000 \text{ lb}$
in SI units $6.89 \times 10^5 \times \frac{258}{10,000} = 17,800 \text{ N}$

The upward force caused by the change of momentum is

$$\begin{aligned} \text{in USCS units} \quad & \frac{1.0 \times \left(\frac{2500 \times 0.32}{40} \right)^2 \times 40}{64.4 \times 2.31} = 107.5 \text{ lb} \\ \text{in SI units} \quad & \frac{1 \times \left(\frac{568 \times 10,000}{258 \times 3600} \right)^2 \times 258}{2 \times 9.81 \times 1.02} = 481 \text{ N} \end{aligned}$$

This is certainly negligible relative to the downward hydraulic axial thrust.

The situation is quite different, however, during the startup of a vertical pump. Although the motor may get up to full speed in just a few seconds, it takes a certain amount of time for the total head to increase from zero that corresponding to the normal operating capacity. Consequently, the pump will be operating in a very high capacity range. Since the upward force caused by the change of momentum varies as the square of the capacity while the downward axial thrust caused by pressure differences is very low, there can be a momentary net upward force, or upthrust. This means that thrust bearings intended to accommodate the axial thrust of vertical pumps must be capable of accommodating some thrust in the upward direction in addition to the normal downward thrust. This is particularly true for pumps with relatively low heads per stage and with short settings because in these units the rotor weight does not at all times compensate for the upthrust from the change in momentum.

Particular care must be exercised in defining the range of vertical movement allowed for the thrust bearings because any such movement must remain within the displacement limits of any mechanical seal used in the pump.

In rather rare cases, a close-coupled vertical pump is operated at such a high capacity that a continuous net upthrust is generated. Such operations can damage the pump because the line shaft is operated in compression and may buckle, causing vibration and bearing wear. The manufacturer's comments should be invited if such an operation is contemplated.

Shaft Elongation in Vertical Pumps The elongation of a vertical pump shaft is caused by three separate phenomena: (1) the tensile stress caused by the weight of the rotor, (2) the tensile stress caused by the axial thrust, and (3) the thermal expansion of the shaft.

In most cases, the tensile stress created by the axial thrust is several times greater than that created by the weight. In a typical example of a 16,000-gpm (3636-m³/h) pump designed for a 175-ft (53.3 m) head and 50 ft (15.25 m) long, the elongation caused by the weight of a 1600-pound (726 kg) impeller will be of the order of 0.0033 in (0.084 mm). The elongation caused by the axial thrust will be approximately 0.0315 in (0.8 mm).

The elongation caused by thermal expansion has to be considered from two angles. First, if the shaft and the stationary parts are built of materials that have essentially the same coefficient of expansion, both will expand equally and no significant relative elongation will take place. Second, if the pumps are operated in essentially the same range of temperatures in which they were assembled, no significant relative expansion will take place, even if dissimilar coefficients of expansion are involved. Whatever the case, the pump manufacturers take these factors into consideration by providing the necessary vertical end-play between the stationary and rotating pump components.

Loads on Foundations of Vertical Pumps If the motor support is integral with the pump discharge column, as in Figures 110, 112, and 113, and if the hydraulic thrust is carried by the motor thrust bearing, this thrust is not additive to the deadweight of the pump and of its motor plus the weight of the water contained in the pump, insofar as the load on the foundations is concerned. This is because the pump and motor mounted in this fashion form a self-contained entity and all internal forces and stresses are balanced within this entity. If the pump and motor are supported separately, however, as in Figure 124, and are joined by a rigid coupling that transmits the pump hydraulic thrust to the motor thrust bearing, the foundations will carry the following loads when the pump is running:

FIGURE 124 The vertical pump and driving motor supported separately (Flowservice Corporation)

- *The foundation supporting the motor:* the weight of the motor plus the weight of the pump rotor plus the axial hydraulic thrust developed by the pump
- *The foundation supporting the pump:* the weight of the pump stationary parts plus the weight of the water in the pump, including the water in the discharge pipe supported by the foundation, less the axial hydraulic thrust developed by the pump

Since when the pump is idle the foundation supporting the pump is not benefited by the reduction in load equivalent to the axial hydraulic thrust, both running and idle operating conditions must be considered in this case.

Typical Arrangements of Vertical Pumps A pump is only part of a pumping system. The hydraulic design of the system external to the pump will affect the overall economy of the installation and can easily have an adverse effect upon the performance of the pump itself. Vertical pumps are particularly susceptible because the small floor space occupied

by each unit offers the temptation to reduce the size of the station by placing the units closer together. If the size is reduced, the suction arrangement may not permit the proper flow of water to the pump suction intake. Recommended arrangements for vertical pumps are discussed in Section 10.1.

SPECIAL PURPOSE PUMPS

In addition to the more or less general purpose pumps described on the preceding pages, literally hundreds of centrifugal pumps are intended for very specific applications. Although it is impossible to describe every one of these special purpose designs, many of them are discussed and illustrated in Sections 9.1 through 9.22, covering a variety of pump services. However, several specific designs are seeing rapidly increasing usage and so are discussed in greater detail here.

Submersible Motor-Driven Wet-Pit Pumps The installation of conventional vertical wet-pit pumps with the motor located above the liquid level may require a considerable length of drive shafting, particularly in the case of deep settings. The addition of this shafting, of the many line bearings, and possibly of an external lubrication system may represent a major portion of the total installed cost of the pumping unit. Furthermore, shaft alignment becomes more critical, and shaft elongation and power losses increase rapidly as the setting is increased, especially for deep-well pumps.

A great variety of submersible motors have been developed to obviate these shortcomings. They are described in Subsection 6.1.1, and a classification of the various types of such motors is presented in Figure 26 of that subsection. Submersible wet-pit pumps eliminate the need for extended shafting, shaft couplings, a mechanical seal or stuffing box, a subsurface motor stand, and, in some cases, an expensive pump house. Both vertical turbine and volute-type wet-pit pumps may be so driven.

Figures 125 and 126 illustrate, respectively, the external appearance and a cross section of a vertical turbine pump driven by a submersible motor located at the bottom of the pump. The pump suction is through a perforated strainer located between the motor and the first-stage impeller bowl. There is, of course, no shafting above the pump and the pump-and-motor unit is supported by the discharge pipe only. No external lubrication is required. The motor is completely enclosed and oil-filled and is provided with a thrust bearing to carry the pump downthrust. A mechanical seal is provided at the motor shaft extension, which is connected to the pump shaft with a rigid coupling. Only a discharge elbow and the electric cable connection are seen above the surface support plate. On occasion, this type of pump is used horizontally as a booster pump in a pipeline, and in such cases the elbow at the discharge is eliminated.

Vertical wet-pit volute-type sump pumps can be obtained with close-coupled submersible motors for drainage, sewage, process, and slurry services. Figure 127 illustrates dual submersible sewage pumps in a below ground collecting tank. The pumps (see Figure 128) are supported by guide rails that make it possible to lower and raise the pumps by means of a chain hoist. During this operation, the discharge pipe is connected and disconnected without dewatering the tank. Other arrangements use foot-supported pumps with rigid discharge piping.

Motors used for this type of construction are usually hermetically sealed, employing a double mechanically sealed oil chamber with a moisture-sensing probe to detect any influx of conductive liquid past the outer seal. Controls to start and stop the pump motors can be either an air compressor bubbler system or level-sensing switches that tilt when floated (refer to Figure 127).

Small portable pumps are available with flexible discharge hoses and built-in water-level motor control switches activated by trapped air pressure. Motors for these pumps are usually oil-filled and have a single mechanical shaft seal but are also available in a hermetically sealed design. The submersible motors are cooled by the liquid in which they are immersed and therefore should not be run dewatered, although some motors can operate for short periods (10 to 15 min.) this way.

FIGURE 125 Vertical turbine pump driven by a submersible motor (Flowserve Corporation)

FIGURE 126 Cross-sectional view of a submersible pump (Flowserve Corporation)

FIGURE 127 Dual submersible sewage pumps in a below ground collecting tank (Flowserve Corporation)

FIGURE 128 A section of a submersible sewage pump shown in Figure 127 (Flowserve Corporation)

In a pump-motor combination (see Figure 129), the motor is cooled by the pumped liquid as it moves through a passage around the sides of the motor. This design also uses a pressurized oil-seal chamber to assure positive sealing.

Sealless Pumps Completely leakproof pumps are available for pumping corrosive, volatile, radioactive, and otherwise hazardous liquids. Canned motor pumps (see Figure 130) are an assembly of a standard centrifugal pump and a squirrel-cage induction motor in a hermetically sealed unit. Modifying a recirculating flow system in a canned motor pump can allow it to be used in applications at up to 1000°F (538°C).

Magnetic drive pumps (see Figure 131) are an assembly of a rotor, an impeller, product lubricated bearings, and a magnetic carrier inside an isolation shell or diaphragm. This rotor is driven by magnets outside the shell or diaphragm. No mechanical connection exists between the driven magnets and the driving magnets. No seals exist and thus we have the term “sealless.” Sealless pumps are described in detail in Subsection 2.2.7.

Straight-Radial-Vane High-Speed Pumps For handling volatile liquids at low flow rates and high heads, the straight-radial-vane impeller in a diffuser casing offers several advantages. Volatile, low-specific-gravity, poor-lubricity liquids require larger running clearances, which is not possible with conventional high-head multistage centrifugal or positive displacement pumps. High-head pumping of these liquids can be handled by operating this completely open impeller at very high speeds through an integral gear increaser and with very large impeller-to-casing clearance, typically 0.030 to 0.070 in (0.76 to 1.8 mm). Tests of one manufacturer's design have shown this clearance can increase to 0.125 in (3.2 mm) with virtually no change in performance, and consequently there is no need to provide adjustment for impeller axial clearance. A pump of this design can also run “dry,” as liquid lubricity is not required to lubricate the bearings, which can be separately lubricated (providing the mechanical seal is lubricated).

Figure 132 illustrates one manufacturer's design of a radial-vane high-speed pump. The impeller rotates in a circular casing that has a single emission point leading to a conical diffusion section. The advantage of this type of casing is that the conversion to pressure occurs outside the circular housing, thus eliminating any recirculation forces that

FIGURE 129 A portable submersible pump (Peabody Barnes)

FIGURE 130 Typical canned motor pump (Ref. Subsection 2.2.7) (Crane Chempump)

would require a close clearance between the impeller and casing. For higher flow ranges, a double emission point design, as shown in Figure 133, is used. This additional emission acts like a double-volute casing in conventional centrifugal pumps.

FIGURE 131 Typical magnetic drive sealless pump (Ref. Subsection 2.2.7) (Flowserve Corporation)

FIGURE 132 A straight-radial-vane impeller in a single emission-point, conical-diffuser circular casing (Sundyne Corporation)

Figure 134 is a sectional view of this pump with an integral speed increaser. Because of the high rotative speed, a single-stage pump can achieve the head normally associated with multistage centrifugal or positive displacement pumps. With this smaller liquid end and an integral gear box, cost and space savings can be appreciable.

FIGURE 133 A straight-radial-vane impeller in a double-emission-point, conical-diffuser circular casing (Sundyne Corporation)

2.2.2

CENTRIFUGAL PUMP PACKING

JAMES P. NETZEL

Packing is used in the stuffing box of a centrifugal pump to control the leakage of the pumped liquid out, or the leakage of air in, where the shaft passes through the casing. This basic form of a seal can be applied in light- to medium-duty services and to those liquids that prove difficult for mechanical seals.

THE DESIGN OF PACKING RINGS

Packing may be referred to as compression, automatic, or floating. Each term describes the type of operation in which the packing will be used.

Automatic and floating packings require no gland adjustments in controlling leakage. Automatic packings are confined to a given space and are activated by the operating pressure. Automatic packing rings are designed in the form of V rings, U cups, and O rings. Floating packing includes piston rings and segmental rings that may be energized by a spring. These types of packing are commonly used in reciprocating applications.

Compression packing is most commonly used on rotating equipment. The seal is formed by the packing being squeezed between the inboard end of the stuffing box and the gland (see Figure 1a). A static seal is formed at the ends of the packing ring and at the inside diameter of the stuffing box. The dynamic seal is formed between the packing and shaft or shaft sleeve. Under a load, the packing deforms down against the shaft, controlling leakage. Some leakage along the shaft is necessary to cool and lubricate the packing. The amount of leakage will depend on the materials of construction for the packing, the operating conditions of the application, and the condition of the equipment.

Packing must be able to withstand equipment variables (see Figure 1b). The design of the packing ring and the materials of construction must be resilient to follow shaft runout and misalignments, as well as to compensate for thermal growth of the equipment without an appreciable increase in leakage.

FIGURE 1 Compression packing; (a) new packing installation, (b) installation variables, (c) installation after many adjustments

As rotating equipment is operated, the load on the packing must be adjusted to control leakage (see Figure 1c). Care should be taken not to overtighten the packing. Most compression packings have a lubricant designed into them to prevent overheating of the packing or scoring of the shaft. Repeated adjustments will drive some of the lubricant from the packing, which will result in reduced operating time.

Compression packings are made of twisted, braided, woven, or wrapped elements formed into square or round cross-sections or other configurations. Square cross-sections are more common for rotating equipment.

A selection of the proper materials for the packing must include the chemical resistance to the product being sealed as well as the temperature, pressure, and shaft speed. Complete lists of the construction materials, packing lubricants and binders are given in Tables 1 and 2.

OPERATING FUNDAMENTALS

The Size and Number of Packing Rings The number of packing rings may vary, depending on the objective of the sealing system or the requirements of the rotating equipment. The most common packing arrangement for rotating equipment is illustrated in Figure 2. Three rings of packing are used to seal the process liquid from the packing lubricant. Two rings between the lantern and gland are used to restrict the leakage of the lubricant to the atmosphere. The size of the packing depends on the size of the equipment. Typically, for rotating shafts, the standard square size packings shown in Table 3 may be considered.

TABLE 1 Common materials of construction for packing

**FIGURE 2** Common packing arrangement

The packing size for an existing piece of equipment can be found by using the formula:

$$\text{Packing size} = \frac{\text{box ID} - \text{shaft or sleeve OD}}{2}$$

TABLE 3 Packing sizes for rotating shafts

| Shaft (or sleeve) Diameter, in (mm) | Packing size, in (mm) |
|---|-----------------------|
| $\frac{5}{8}$ to $1\frac{1}{8}$ (15 to 30) | $\frac{1}{4}$ (6.3) |
| $1\frac{1}{8}$ to $1\frac{7}{8}$ (30 to 50) | $\frac{5}{16}$ (8) |
| $1\frac{7}{8}$ to 3 (50 to 75) | $\frac{3}{8}$ (10) |
| 3 to $4\frac{3}{4}$ (75 to 120) | $\frac{1}{2}$ (12.5) |
| $4\frac{3}{4}$ to 12 (120 to 305) | $\frac{5}{8}$ (16) |

FIGURE 3 A smothering gland and water-cooled stuffing box

For packing to operate properly, the finish on the shaft sleeve must be at least 16 μin (0.4 μm) centerline average (CLA) and the finish in the bore should be 63 μin (1.65 μm) CLA. The sleeve *must* be harder than the packing and chemically resistant to the liquid being sealed. If the sleeve has a coated material for a hard-wear surface, the sleeve must also have good thermal shock resistance.

Lantern Rings (Seal Cages) When an application requires that a lubricant be introduced to the packing, a lantern ring is used to distribute the flow (refer to Figure 2). This ring is used at or near the center of the packing installation. For ease of assembly, most lantern rings are axially split. The construction materials range from metal to TFE (tetrafluoroethylene). TFE lantern rings are usually filled with glass or with glass and molybdenum disulfide. They are inherently self-lubricating and will not score the shaft. A throat bushing at the bottom of the stuffing box can be used to provide a closer clearance with the shaft to prevent packing extrusion.

Stuffing Box Gland Plates All mechanical packings are mechanically loaded in the axial direction by the stuffing box gland (refer to Figure 2). In cases where leakage of the process liquid is dangerous or can vaporize and create a hazard to operating personnel, a smothering gland is used to introduce a neutral liquid at lower temperatures (see Figure 3). A sufficient quantity of quenching liquid should be used to eliminate the danger from the liquid being pumped. The neutral liquid circulated in the gland mixes with the leakage and carries it to a safe place for disposal. Close clearances in the gland control the leakage of the combined liquids to the atmosphere. This quench can also be used to protect the packing from any wear through abrasion, because the leakage cannot vaporize and leave behind abrasive crystals.

TABLE 4 Leakage to prevent packing burning and sleeve scoring

| Pressure lb/in ² (bar) | Leakage, drops/min | cc/min |
|-----------------------------------|--------------------|--------|
| 0–60 (0–4.0) | 60 | 4 |
| 61–100 (4.1–6.8) | | 190 |
| 101–250 (6.9–17) | | 470 |

TABLE 5 Typically coefficients of friction

| Material | <i>f</i> |
|-----------------------|----------|
| Plain cotton | 0.22 |
| TFE impregnated fiber | 0.17 |
| Grease-lube fiber | 0.10 |
| Flexible graphite | 0.05 |

Glands are usually made of bronze, but cast iron or steel can be used for all-iron pumps. When iron or steel glands are used, they are normally bushed with a non-sparking material like bronze.

Leakage and Power Consumption The basic operating parameters for compression packing are the PV (pressure × velocity) factor and the projected bearing area of the assembly. Together they determine the rate of heat generation for the system. Some leakage of the product being sealed or of the packing lubricant is necessary to keep the packing from burning up or scoring the shaft sleeve. The minimum values for leakage at different packing pressures are given in Table 4. Flexible graphite and carbon filament compression packings can be used with reduced leakage rates, or in dry, gas-tight pump stuffing boxes, as the developed heat is dissipated through the packing and pump housing.

The exact pressure *P* between the shaft sleeve and the packing is a function of the pressure distribution over the length of the packing and the axial loading from the gland. For ease of calculation when determining the PV value, the gage pressure of the liquid at the packing is multiplied by $\pi \times$ the packing ID \times rpm. The heat generation at the packing can then be estimated as

$$Q = \frac{f\pi^2 PND^2 L}{CJ}$$

where *Q* = heat generated, Btu/min (W)

f = coefficient of friction

P = liquid pressure at packing, lb/in² gage (bar)

N = shaft speed, rpm

D = sleeve OD or packing ID, in (m)

L = sleeve length covered by packing, in (m)

C = 12 (60 for SI units)

J = mechanical equivalent of heat = 778 ft · lb/Btu (1 N · m/s · W)

The coefficient of friction for various packings at a pressure of 100 lb/in² (6.8 bar) is given in Table 5. The heat generated by the packing must be removed by the leakage through the packing.

APPLICATION INFORMATION AND SEALING ARRANGEMENTS

Materials of Construction Basically, stuffing box packing is a pressure breakdown device. In order for a packed stuffing box to operate properly, the correct packing must be

FIGURE 4 Graphite acrylic packing in continuous form (John Crane Inc.)

FIGURE 5 Non-asbestos packing (John Crane Inc.)

FIGURE 6 Flexible graphite packing rings (John Crane, Inc.)

applied and the appropriate design features must be included in the system. Numerous types of packing materials are available, each is suited to a particular service. These may be grouped into three categories:

1. **Non-asbestos packing** Since asbestos is no longer available as a packing material, other types of packing material are being used. These include cotton, TFE filament, Aramid fiber, aromatic polyamides, graphite/carbon yarn, and flexible graphite. All of these materials, with the exception of flexible graphite, can be impregnated with various lubricants. An example of graphited acrylic packing is shown in Figure 4. With the exception of flexible graphite, all the materials are of an interlaced construction for greater flexibility (see Figure 5). Packing made with this type of construction remains intact even if individual yarns wear away at the inside diameter of the packing.
2. **Flexible graphite** These types of packing rings were originally available cut from laminated sheet stock that required the rings to be made with an interference fit. Flexible graphite rings are made today from ribbon tape that is easily compressed to the shaft and bore to affect a better seal. Flexible graphite rings are available in split or endless rings (see Figure 6) or as the ribbon tape itself for ease of maintenance and installation. Operating limits for non-asbestos packings are found in Table 6.
3. **Metallic packing** The basic materials of construction are lead or babbitt, aluminum, and copper in either wire or foil form. Metallic packing rings have flexible cores of non-asbestos materials such as twisted glass fiber. The packing is impregnated with graphite grease and/or oil lubricants (see Figures 7 and 8). Babbitt is used in water and oil services at temperatures up to 450°F (229°C) and pressures up to 250 lb/in² (17 bar). Copper foil is used with water and low sulfur oils. Aluminum

TABLE 6 Service limitations of common packing materials^a

| Packing Material | Pressure (max.) ^b lb/in ² gage (bar) | PV rating (max.) ^c lb/in ² gage · fpm (bar · m/s) | Temp. (max.) ^d °F (°C) | pH Range | Comments |
|--|---|--|---|-------------|---|
| Cotton | 100 (6.8) | | 150(65.6) | 5–7 | Non-abrasive material; for cold water and dilute salt solutions |
| Flax/ramie | 100 (6.8) | 188,000 (65.8) | 150 (65.6) | 5–7 | High, wet strength and excellent resistance to fungi and rotting; for cold water and dilute salt solutions |
| Plastic | 100 (6.8) 250 (17) | 188,000 (65.8) 471,000 (165) | 600 (315.5) 150 (65.6) | 4–8 | Excellent sealing qualities, reacts well to gland adjustments, can extrude at higher pressure if not backed up by braided or metallic packing |
| Graphited acrylic | 250 (17) | 471,000 (165) | 350 (175) | 4–8 | For mild chemicals and solvents |
| Acrylic TFE- impregnated | 250 (17) | 471,000 (165) | 350 (175) | 2–10 | For mild chemicals and solvents |
| Babbitt (lead) | 250 (17) | 471,000 (165) | 450(232.2) | 2–10 | Shaft sleeve must have a Brinell hardness of 500 or more; for hot oils and boiler feed water |
| Aluminum or copper | 250 (17) | 471,000 (165) | 750 (398.8) | 3–10 | Shaft sleeve must have a Brinell hardness of 500 or more; for hot oils and boiler feed water |
| TFE filament | 250 (17) | 471,000 (165) | 500 (260) | 0–14 | For corrosive liquids and food service; usually requires slightly higher break-in leakage |
| Aramid fiber | 250 (17) | 471,000 (165) | 500 (260) | 3–11 | Strong resilient packing; maximum speed 1,900 fpm (9.6 m/s); good in abrasives and chemicals |
| Graphite/carbon filament ^e | 250 (17) | 471,000 (165) | 750 (398.8) | 0–14 | For corrosive liquids and high- temperature applications |
| Flexible Graphite ^f | 250 (17) | 471,000 (165) | 1000 (540) | 0–14 | Excellent conductor of heat from the sealing surfaces; operates with minimum leakage; excellent radiation resistance |

(a) Continuous lubrication introduced at the lantern ring. This table is only a guide. Consult the packing manufacturer with complete operating conditions for exact recommendations.

(b) Pressure relates to the operating pressure at the stuffing box.

(c) PV data based on a 2 in (5.08 cm) shaft at 1,750 and 3,600 rpm.

(d) Temperature is the product temperature.

(e) Functional temperature. Graphite can be used up to 3000°F (1650°C) in non-oxidizing atmospheres.

(f) Functional temperature. Flexible graphite can be used to 5300°F (2970°C) in non-oxidizing atmospheres.

FIGURE 7 Metallic packing in spiral form (John Crane Inc.)

FIGURE 8 Metallic packing in ring form (John Crane Inc.)

is used in oil service and heat transfer fluids. Both copper and aluminum have a temperature range up to 1000°F (537°C) and pressures of 250 lb/in² (17 bar). Babbitt is not suitable for running against brass or bronze shaft sleeves, and where copper or aluminum is used, the sleeves should be 550 Brinell (55–60 Rockwell C) or harder.

Additional service limitations for common packing materials can be found in Table 6.

ENVIRONMENTAL LIMITATIONS

Pressure Every pumping application results in either positive or negative pressure at the throat of the pump stuffing box. A positive pressure will force the liquid pumped through the packing to the atmosphere side of the pump. Higher pressure will result in greater leakage from the pump. This results in excessive tightening of the gland, which causes accelerated wear of the shaft or shaft sleeve and packing. For pressures at the stuffing box greater than 75 lb/in² (5.1 bar), some means of throttling the pressure should be considered. A combination of hard and soft rings die-formed to the exact stuffing box bore

FIGURE 9 Combination of hard and soft packing (John Crane Inc.)

FIGURE 10 Compression packing with throttle bushing for pressure breakdown

and sleeve dimensions can be used (see Figure 9). Harder rings at the inboard end of the box and at the lantern ring and gland break down the pressure and prevent the extrusion of the packing.

If the packing itself cannot be used to break down the pressure, then a throttle bushing must be used (see Figure 10). This is a typical arrangement for a vertical turbine pump where the stuffing box is subject to the discharge pressure of the pump. Here the throttle bushing is used to bring the liquid to almost suction pressure, and most of the leakage through the bushing is bled back to the suction. When the suction pressure is less than atmospheric, as in condensate pump service, an orifice is used in the piping back to the suction in order to maintain pressure above atmospheric pressure in the stuffing box. This prevents air leakage into the pump and excessive flow and wear at the bushing.

When a pump is fitted with a bypass line from the discharge, a valve can also be used to reduce the pressure at the stuffing box. This is another method for reducing pressure for the benefit of the installation.

Air Leakage When the pressure at the stuffing box is atmospheric or just below during normal operation, a bypass from the pump casing discharge through an orifice can be used to inject liquid into the lantern ring. The sealing liquid will flow partly into the pump and partly out to the atmosphere, thereby preventing air from entering at the stuffing box. This arrangement is commonly used to handle clean, cool water. In some pumps, these connections are arranged so that liquid can be introduced into the lantern ring through internally drilled passages.

When the negative pressure is very low, such as when the suction lift is in excess of 15 ft (4.6 m), an independent injection of 10 to 25 lb/in² (4.8 to 11.7 bar) higher than the atmospheric pressure must be used on the pump. Otherwise, priming may be difficult. Hot well pumps or condensate pumps operate with as much as 28 in (0.7 m) of vacuum, and air leakage into the pump would occur even on standby service. Here a continuous injection of clean, cool water is required, or alternatively, a cross connection of sealing water to another operating pump will provide sealing pressure as long as one pump is operating. A lantern ring is provided for this, as shown in Figure 10.

Temperature The control of temperature at the stuffing box is an important factor in promoting the life of the packing. Even though packings are rated for high product temperatures, cooling in most cases is desirable. The heat developed at the packing must also be removed. The rules of thumb are as follows:

- For light service conditions with pressures at 15 lb/in² (1 bar) and temperatures at 200°F (90°C), cooling is desirable.
- For medium service conditions with pressures at 50 lb/in² (3.4 bar) and temperatures at 250°F (118°C), lantern ring cooling is desirable, such as one gpm (3.78 l/min) at 5 lb/in² (0.34 bar) above process pressure.
- For high service conditions with pressures at 100 lb/in² (6.8 bar) and temperatures at 300°F (131°C), lantern ring cooling is desirable, such as one gpm (3.78 l/min) at 5 lb/in² (0.34 bar) above process pressure plus a water-cooled stuffing box (refer to Figure 3).

When cooling water is required, it is circulated through the stuffing box at the lantern ring. For horizontal-shaft pumps, the inlet should be at the bottom, with the outlet at the top of the stuffing box. Some of the coolant may flow to the process liquid and some to the atmosphere. The outboard packing rings seal only the cool liquid.

If the product to be sealed will solidify, then the packing box will have to be heated before the pump is started. This can be accomplished by steam or electric tracing of the pump stuffing box.

Abrasives Liquids that contain abrasives in the form of *suspended solids* such as sand and dirt will shorten the life of the packing. Particles will imbed themselves in the packing and will begin to wear the shaft or shaft sleeve. Abrasives can be eliminated at the sealing surfaces by injecting a clean liquid into the lantern ring. The injection may take the form of a bypass line from the pump discharge through a filter or centrifugal separator. Where necessary, the clean injection may also be from an external source.

To keep the abrasives from the packing in horizontal-shaft pumps, the injection can be made directly to the inboard end of the stuffing box through the lantern ring (see Figure 11). A soft rubber gasket between the lantern ring and the box shoulder can be used to limit the flow of clean liquid and the ingress of abrasives.

When separators and filters cannot be used, an injection from an external source must be considered. Two rings of packing are located between the lantern ring and the inboard end of the stuffing box to keep the product dilution to a minimum. External flushing should be injected into the stuffing box at a pressure 10 to 25 lb/in² (1.7 bar) greater than the pressure at the inboard end of the box from the liquid being pumped. A regulating valve, illustrated in Figure 12, can be used to control the pressure and flow to the packing installation. Flow to the packing can be regulated to ensure the best operating environment for this seal, while conserving water used for injection.

FIGURE 11 A clean injection through a centrifugal separator to keep abrasives out of the stuffing box

Packing or Single Seal Flush

FIGURE 12 A regulation valve that controls and monitors the flow of water to the packing (Safematic)

Dissolved solids in the liquid being pumped can also create a wear problem. Here an increase or decrease in stuffing box temperatures may be necessary to keep solids in solution.

INSTALLING CONTINUOUS COIL PACKING

To install continuous coil packing, perform the following steps:

1. Loosen and remove the gland from the stuffing box.
2. Using a packing puller, begin to remove the old packing rings.
3. Remove the split lantern ring (if present) and then continue removing the packing with the puller.
4. After the packing has been removed, check the sleeve for scoring and nicks. If the shaft sleeve or shaft cannot be cleaned up, it must be replaced. Check the size of the

stuffing box bore and the shaft sleeve or shaft diameter to determine which size packing should be used.

5. After the size of the packing has been determined, wrap the packing tightly around a mandrel, which should be the same size as the pump shaft or sleeve. The number of coils should be sufficient to fill the stuffing box. Cut the packing along one side to form the individual rings.
6. Before beginning the assembly of any packing material, be sure to read all the instructions from the manufacturer. Assemble the split packing rings on the pump. Each ring should be sealed individually with the split ends staggered 90° and the gland tightened to seal and fully compress the ring. Be sure the lantern ring is reinstalled correctly at the flush connection. Then back off the gland and retighten it, but only finger-tight. The exception to this procedure is that TFE packing should be installed one ring at a time, but not seated because TFE packings have high thermal expansion.
7. Allow excess leakage during break-in to avoid the possibility of rapid expansion of the packing, which could score the shaft sleeve or shaft so that leakage could not be controlled.
8. Leakage should be generous upon startup. If the packing begins to overheat at startup, stop the pump and loosen the packing until leakage is obtained. Restart only if the packing is leaking.

CAUSES FOR A SHORT PACKING LIFE

In order for packing to operate properly, the equipment must be in good condition. Shafts should be checked for runout and eccentricity to be sure they are within the manufacturer's recommended tolerances. Surfaces in contact with the packing should be finished to the correct smoothness and tolerance. Table 7 lists common troubles that affect the packing life. Causes and possible cures are also given.

TABLE 7 Packing troubles, causes, and cures

| Trouble | Cause | Cure |
|---------------------------------------|---|---|
| No liquid delivered by pump | Lack of prime (packing loose or defective, to allowing air leak into suction) | Tighten or replace packing and prime pump. |
| Not enough liquid delivered by pump | Air leaking into stuffing box | Check for leakage through stuffing box while operating. If no leakage occurs after after reasonable gland adjustment, new packing may be needed. or Lantern ring may be clogged or displaced and may need centering in line with sealing liquid connection. or Sealing liquid line may be clogged. or Shaft or shaft sleeve beneath packing may be badly scored, allowing air to be sucked into pump. |
| | Defective packing | Replace packing and check the smoothness of the shaft or shaft sleeve. |
| Not enough pump pressure | Defective packing | As per preceding |
| Pump works for a while and then quits | Air leaks into stuffing box | As per preceding |
| Pump takes too much power | Packing too tight | Release gland pressure and retighten reasonably. Keep leakage flowing. If none, check packing, sleeve, or shaft. |
| Pump leaks excessively at stuffing | Defective packing | Replace worn packing or replace packing damaged by lack of lubrication. |
| | Wrong type of packing | Replace packing not properly installed or run in. Replace improper packing with correct grade for liquid being handled. |
| | Shaft or shaft sleeve scored | Put in lathe and machine-true and smooth or replace. Recheck dimensions for correct packing size. |
| Stuffing box overheats | Packing too tight | Release gland pressure and retighten. |
| | Packing not lubricated | Release gland pressure and replace all packing if any burnt or damaged. |
| | Wrong grade of packing | Check with pump or packing manufacturer for correct grade. |
| | Insufficient cooling water to jacket | Check for open supply line valve or clogged line. |
| | Stuffing box improperly packed | Repack. |
| Packing wears too fast | Shaft or shaft sleeve worn or scored | Remachine or replace. |
| | Insufficient or no lubrication | Repack, making sure packing is loose enough to allow some leakage. |
| | Packing packed improperly | Repack properly, making sure all old packing is removed and the box is clean. |
| | Wrong grade of packing | Check with pump or packing manufacturer. |
| | Pulsating pressure on external seal liquid line | Remove cause of pulsation. |

2.2.3

CENTRIFUGAL PUMP MECHANICAL SEALS

JAMES P. NETZEL

Mechanical seals have been used for many years to seal any number of liquids at various speeds, pressures, and temperatures. Today plant operators are benefiting from improved seal technologies driven by the U.S. Clean Air Act of 1990, and the American Petroleum Institute (API) Standard 682. These new seal technologies are based on advanced computer programs used to optimize seal designs, which are then verified through performance testing at simulated refinery conditions required by the API. The results to date indicate not only an improvement in emissions control, but also a major increase in equipment reliability.

CLASSES OF SEAL TECHNOLOGY

Emerging seal technologies are providing clear choices for sealing. Various plant services require the application of these new technologies for emissions control, safety, and reliability. Sealing systems are now available that are based on the preferred method of lubrication to be used. These classes of seals are as follows:

1. Contacting liquid lubricated seals:

- Normally, a single seal arrangement is cooled and lubricated by the liquid being sealed. This is the most cost-effective seal installation available to the industry.
- Dual seals are arranged to contain a pressurized or non-pressurized barrier or buffer liquid. Normally, this arrangement will be used on applications where the liquid being sealed is not a good lubricating fluid for a seal and for emissions containment. These arrangements require a lubrication system for the circulation of barrier or buffer liquids.

2. Non-contacting gas lubricated seals:

- Dual non-contacting, gas-lubricated seals are pressurized with an inert gas such as nitrogen.
- Dual non-contacting, gas-lubricated seals are used in a tandem arrangement and pressurized by the process liquid being sealed, which is allowed to flash to a gas at the seal. A tandem seal arrangement is used on those liquids that represent a danger to the plant environment. For non-hazardous liquids, a single seal can be used.

Each of these solutions has been used on difficult applications to increase the *mean time between maintenance* (MTBM).

SEAL DESIGN

Advancing the state-of-the-art sealing systems are new suites of computer programs such as C'Stedy^{SM(1)} used to analyze the performance of both contacting and non-contacting seal designs during steady-state and transient conditions. This type of finite analysis considers all of the operating conditions, the fluid sealed, the materials of construction, and seal geometry. The outputs from the program are seal distortion, temperature distribution, friction power, actual *PV* (pressure \times velocity), leakage, the percentage of face in liquid or vapor, and fluid film stability (see Figure 1). This type of analysis requires accurate fluid and material properties. The results from the program can predict the success or failure of a given installation.

For example, a mixture of liquid hydrocarbon made up of ethane, propane, butane, and hexane has to be sealed. This is a new application. The operating condition is 1,300 psig at 70°F. The shaft speed is 3,600 rpm. To determine the performance of this seal prior to installation, an analysis must be made. The results of this study indicate stable operations for a contacting seal, as shown in Figure 2. This study was used to predict seal performance. Actual field results from this difficult service were excellent at startup and during equipment operation.

FIGURE 1 C'StedySM fluid film model for a mechanical seal (John Crane Inc.)

¹Service Mark of John Crane Inc.

FIGURE 2 C'Steady output for a successful seal on high pressure light hydrocarbon service (John Crane Inc.)

FIGURE 3 The basic components of a mechanical seal

These state-of-the-art computer tools not only predict performance, but they also can be used to determine any short seal life. By using a series of calculations per second, this type of analysis can be used to create an animation that will visibly show changes to a seal at startup and during fluctuations in operating conditions. A seal can be examined for stable and unstable operations. This is a useful analysis tool for critical applications.

DESIGN FUNDAMENTALS

Contacting Liquid Lubricated Seals The basic components of a mechanical seal are the primary and mating rings. Together they form the dynamic sealing surfaces, which are perpendicular to the shaft. The primary ring is part of the seal head assembly, while the mating ring and static seal form a second assembly, making a complete installation for a pump. These basic seal parts are shown in Figure 3. For slower and normal shaft speeds, the seal head assembly will rotate with the shaft, while on high shaft speeds, the seal head assembly will be held stationary to the equipment.

The only difference between contacting and non-contacting seal technologies is found in the design of the seal faces. Each system has the same type and number of parts. Each has its own area of application for maximum sealing efficiency. Non-contacting seal technology will be discussed later.

FIGURE 4 Processes involved at contacting seal faces

In a contacting seal, as the shaft begins to rotate, a small fluid film develops, along with frictional heat from the surfaces in sliding contact. These processes occurring at the seal faces are shown in Figure 4. The amount of heat developed at the seal faces must be removed to prevent the liquid being sealed from flashing or beginning to carbonize. Seal heat can be removed with a seal flush located at the seal faces. To analyze the performance of a seal and determine amount of cooling, the following calculations can be made.

Seal Balance The greatest concern to the seal user is the dynamic contact between the mating seal surfaces. The performance of this contact determines the effectiveness of the seal. If the load at the seal faces is too high, the liquid at the seal faces will vaporize or carbonize and the seal faces can wear out. Damage to the seal faces can occur due to unstable conditions. A high wear rate from solid contact and leakage can occur if the bearing limits of the materials are exceeded. Seal balancing is a feature that is used to avoid these conditions and provide for a more efficient installation.

The pressure in any seal chamber acts equally in all directions and forces the primary ring against the mating ring. Pressure acts only on the annular area a_c (see Figure 5a), so that the force in pounds (Newtons) on the seal face is as follows:

$$F_c = pa_c$$

where p = seal chamber pressure, lb/in² (N/m²) and

a_c = hydraulic closing area, in² (m²)

The pressure in lb/in² (N/m²) between the primary ring and mating ring is

$$P'_f = \frac{F_c}{a_o} = \frac{pa_c}{a_o}$$

where a_o = hydraulic opening area (seal face area), $\text{in}^2(\text{m}^2)$.

To relieve the pressure at the seal faces, the relationship between the opening and closing forces can be controlled. If a_o is held constant and a_c is decreased by a shoulder on a sleeve or seal hardware, the seal face pressure can be lowered (see Figure 5b). This is called *seal balancing*. A seal without a shoulder in the design is referred to as an *unbalanced seal*. A balanced seal is designed to operate with a shoulder.

The ratio of the hydraulic closing area to the face area is defined as seal balance b :

$$b = \frac{a_c}{a_o}$$

Seals can be balanced for pressure at the outside diameter of the seal faces, as shown in Figure 5b. This is typical for a seal mounted inside the seal chamber. Seals installed outside the seal chamber can be balanced for pressure at the inside diameter of the seal faces. In special cases, seals can be double-balanced for pressure at both the outside and inside diameters of the seal. Seal balances can range from 0.65 to 1.35, depending on operating conditions.

Face Pressure As relative motion takes place between the seal planes, a liquid film develops. The generation of this film is believed to be the result of surface waviness in the individual sealing planes. Pressure and thermal distortion, as well as anti-rotation devices such as drive pins, keys, or dents used in the seal design, have an influence on surface waviness and on how the film develops between the sliding surfaces. Hydraulic pressure develops in the seal face, which tends to separate the sealing planes. The pressure distribution, referred to as a pressure wedge, shown in Figure 6, can be considered as linear, concave, or convex. The actual face pressure p_f in lb/in^2 (N/m^2) is the sum of the hydraulic pressure p_h and the spring pressure P_{sp} designed into the mechanical seal. The face pressure P_f is a further refinement of P'_f , which does not take into account the liquid film pressure or the mechanical load of the seal:

FIGURE 5 Hydraulic pressure acting on the primary ring: a) unbalanced, b) balanced

FIGURE 6 The pressure distribution can be considered linear, concave, or convex.

$$P_f = P_h + P_{sp}$$

where $P_h = \Delta p(b-k)$, lb/in²(N/m²) and

Δp = pressure differential across seal face, lb/in² (N/m²)

k = pressure gradient factor

b = seal balance

The mechanical pressure for a seal design is

$$P_{sp} = \frac{F_{sp}}{a_o}, \text{ lb/in}^2 \text{ (N/m}^2\text{)}$$

where F_{sp} = seal spring load, lb (N) and

a_o = seal face area, in² (m²)

Then the actual face pressure can be expressed as

$$P_f = \Delta p(b - k) + P_{sp}$$

The actual face pressure is used in the estimate of the operating pressure and velocity for a given seal installation.

Pressure-Velocity As the sealing planes move relative to each other, they are affected by the actual face pressure and rotational speed. The product of the two, pressure times velocity, is referred to as PV and is defined as the power N_f per unit area with a coefficient of friction of unity:

$$PV = \frac{N_f}{a_o}$$

For seals, the equation for PV can be written as follows:

$$PV = P_f V_m = [\Delta p(b - k) + P_{sp}] V_m$$

where V_m = velocity at the mean face diameter d_m , ft/min (m/s).

The PV for a given seal installation can be compared with values developed by seal manufacturers as a measure of adhesive wear.

Power Consumption The PV value also enables the seal user to estimate the power loss at the seal with the following equation:

$$N_f = (PV) f a_o, \text{ ft} \cdot \text{lb/min (N} \cdot \text{m/s)}$$

where f is the coefficient of friction.

As a rule of thumb, the power to start a seal is generally five times the running value. The coefficients of friction for various common seal face materials are given in Table 1. These coefficients were developed with water as a lubricant at an operating PV value of 100,000 lb/in² · ft/min (35.03 bar · m/s). The coefficient of friction is a function of the tribological properties of the mating pairs of seal face materials and the fluid being sealed. Values in oil would be slightly higher because of the viscous shear of the fluid film at the seal faces. For a double or tandem seal, the barrier/buffer oil should have a low viscosity and be a good lubricant. The values given are suitable for estimating the power loss in a seal.

For example, let's say we have a pump having a 2-in (50.8-mm) diameter sleeve at the seal chamber is fitted with a balanced seal of this size and mean diameter. The seal operates in water at 300 lb/in² (20.68 bar), 3,600 rpm, and ambient temperatures. The materials of construction are carbon and tungsten carbide. Determine the PV value and power loss of the seal, given the following:

TABLE 1 Coefficient of friction for various seal face materials (John Crane Inc.)

| Sliding Materials | | Coefficient of friction |
|-----------------------------------|----------------------------------|-------------------------|
| Rotating | Stationary | |
| Carbon-graphite (resin filled) | Cast iron | 0.07 |
| | Ceramic | 0.07 |
| | Tungsten carbide | 0.07 |
| | Silicon carbide | 0.02 |
| | Silicon carbide converted carbon | 0.015 |
| Silicon carbide | Tungsten carbide | 0.05 |
| Silicon carbide | Silicon carbide converted carbon | 0.04 |
| | Silicon carbide converted carbon | 0.05 |
| | Silicon carbide | 0.05 |
| | Tungsten carbide | 0.01 |

$$\Delta p = 300 \text{ lb/in}^2 (20.68 \text{ bar})$$

$$b = 0.75$$

$$k = 0.5$$

$$d_m = 2 \text{ in (50.8 mm)}$$

$$P_{sp} = 25 \text{ lb/in}^2 (1.72 \text{ bar})$$

$$V_m = \frac{\pi}{12} \times 2 \times 3600 = 1885 \text{ ft/min} \left(\frac{\pi \times 50.8 \times 3600}{1000 \times 60} = 9.57 \text{ m/s} \right)$$

$$a_o = 0.4 \text{ in}^2 (0.000258 \text{ m}^2)$$

$$f = 0.07 \text{ (Table 1)}$$

In USCS units:

$$PV = [300(0.75 - 0.5) + 25](1885) = 188,400 \text{ lb/in}^2 \cdot \text{ft/min}$$

$$N_f = (188,400)(0.07)(0.4) = 5275 \text{ ft} \cdot \text{lb/min} = 0.16 \text{ hp}$$

In SI units:

$$PV = [20,68(0.75 - 0.5) + 1.72](9.57) = 66 \text{ bar} \cdot \text{m/s} = 66 \times 10^5 \text{ N/m}^2 \cdot \text{m/s}$$

$$N_f = (66 \times 10^5)(0.07)(2.58 \times 10^{-4}) = 119 \text{ N} \cdot \text{m/s} = 119 \text{ W}$$

Temperature Control Controlling the temperature at the seal faces is desirable because wear is a direct function of temperature. Heat at the seal faces also causes thermal distortion, which will contribute to increased seal leakage. Many applications require some type of cooling.

The temperature of the sealing surfaces is a function of the heat generated by the seal, plus the heat gained or lost to the pumpage. The heat generated at the faces from sliding contact is the mechanical power consumption of the seal being transferred into heat. Therefore,

$$Q_s = C_a N_f = C_1 (PV f a_o)$$

where Q_s = heat input from the seal, Btu/h(W) and

$$C_1 = 0.077 \text{ for USCS units and } 1 \text{ for SI units}$$

If the heat is removed at the same rate it is produced, the temperature will not increase. If the amount of heat removed is less than that generated, the seal face temperature will

FIGURE 7 Unbalanced seal heat generation (John Crane Inc.)

increase to a point where seal face damage will occur. The estimated values for heat input are given in Figures 7 and 8.

Heat removal from a single seal is accomplished by a seal flush. The seal flush is usually a bypass from the discharge line on the pump or an injection from an external source. The flow rate for cooling can be found by calculating the following:

$$\text{gpm (m}^3/\text{h)} = \frac{Q_s}{C_2(\text{sp. ht.})(\text{sp. gr.})\Delta T}$$

where Q_s = seal heat, Btu/h(W)

C_2 = 500 in USCS units and 1,000 in SI units

sp. ht. = specific heat of coolant, Btu/lb. °F (J/kg · K)

sp. gr. = specific gravity of coolant

ΔT = temperature rise, °F (K)

When handling liquids at elevated temperatures, the heat input from the process must be considered in the calculation of coolant flow. Thus,

$$Q_{\text{net}} = Q_p + Q_s$$

The heat load Q_p from the process can be determined from Figure 9.

As an example, let's determine the net heat input for a 4-in (102-mm) diameter balanced seal in water at 1,800 rpm. The pressure and temperature are 400 lb/in² (27.6 bar) and 170°F (76.7°C). From Figure 8, we have the following:

In USCS units:

$$Q_s = (3500 \text{ Btu/h/1000 rpm}) \times (1800) = 6300 \text{ Btu/h}$$

FIGURE 8 Balanced seal heat generation (John Crane Inc.)

In SI units:

$$Q_s = (1025 \text{ W/1000 rpm}) \times (1800) = 1845 \text{ W}$$

From Figure 9, assuming that the seal chamber will be cooled to 70°F (21°C) and that the temperature difference between the seal chamber and pumpage is 100°F (37.8°C), we have the following:

In USCS units: $Q_p = 255 \text{ Btu/h}$

In USCS units: $Q_p = 75 \text{ W}$

$\therefore Q_{net} = 6555 \text{ Btu/h (1920 W)}$

The total heat input can be used to estimate the required flow to the seal. When multiple seals are used in a pump seal chamber, the heat load from each seal must be considered as well as any heat soak from the process.

Different methods are used to supply cool liquid to the seal chamber (see Figure 10). When the liquid is clean, an internal flush connection at (A) can be used to cool the seal. When the liquid is dirty, an external flush at (B) can be used. This will allow the flush, a bypass from the discharge line, to pass through a filter or centrifugal separator. The seal faces will be flushed with clean, cool liquid. Increased pressure from the flush provides positive circulation and prevents flashing at the seal faces caused by the heat generation.

When a pump handles liquids near their boiling point, additional cooling of the seal chamber is required. A typical arrangement to accomplish this is shown in Figure 11. This seal is equipped with a pumping ring and a heat exchanger. The pumping ring acts as a miniature pump, causing the liquid to flow through the outlet piping at the top of the seal

FIGURE 9 Heat soak from process when water is used for lubrication (John Crane Inc.)

FIGURE 10 Cooling circulation to mechanical seal: (A) internal circulation plug port, (B) external circulation plug port

FIGURE 11 High performance boiler feed pump seal with external cooling

chamber. The liquid passes through the heat exchanger and returns directly to the faces at the bottom inlet in the end plate. As the liquid is circulated, heat is removed from the seal and seal chamber. A closed loop system is commonly used on hot water pumps. This method is extremely efficient since the coolant is circulated only in the seal chamber and does not reduce the temperature of the liquid in the pump.

It should be noted that during periods of shutdown different wear problems might exist because the seal faces may be too cold. The product being pumped may be a solution that can crystallize or solidify at ambient temperatures. For these applications, the seal faces may have to be preheated before starting to avoid damage to the seal.

Leakage Leakage is affected by the parallelism of the sealing planes, angular misalignment, coning (negative face rotation), thermal distortion (positive face rotation), shaft runout, axial vibration, and fluctuating pressure. For parallel faces only, which take into account seal geometry only, the theoretical leakage in cubic centimeters per hour can be estimated from the following:

$$Q_3 = -C_3 \times h^3(P_2 - P_1)/u \ln(R_2/R_1)$$

where $C_3 = 2.13 \times 10^{10}$ in USCS units and 1.88×10^9 in SI units

h = face gap, in (m)

P_2 = pressure at face ID, lb/in² (N/m²)

P_1 = pressure at face OD, lb/in² (N/m²)

u = dynamic viscosity, C_p (N · s/m²)

R_2 = outer face radius, in (m)

R_1 = inner face radius, in (m)

Negative leakage indicates flow from the face's outer diameter to the inner diameter. The effect of centrifugal force from one of the rotating sealing planes is very small and can be neglected in normal pump applications. The gap between the seal face is a function of the materials of construction, flatness, and the liquid being sealed. The face gap can range from 20×10^{-6} to 50×10^{-6} in (0.508×10^{-6} to 1.27×10^{-6} m).

Contacting Seal Operating Envelope Every seal has an operating envelope. The basic envelope for a contacting seal is shown in Figure 12. The upper limits are defined by wear of the seal faces, usually defined by a pressure-velocity limit. The fluid being sealed should be cooled so the liquid at the seal faces does not flash. Operating within the envelope will result in excellent seal performance.

FIGURE 12 Operating envelope for a contacting seal

CLASSIFICATION OF SEALS BY ARRANGEMENT

Sealing arrangements can be classified into two groups:

1. Single seal installations
 - a. Internally mounted
 - b. Externally mounted
2. Multiple seal installations
 - a. Double seals
 - b. Tandem seals

Single seals are used in most applications. This is the simplest seal arrangement with the least number of parts. An installation can be referred to as *inside-mounted* or *outside-mounted*, depending on whether the seal is mounted inside or outside the seal chamber (see Figure 13). The most common installation is an inside-mounted seal. Here the liquid under pressure acts with the spring load to keep the seal faces in contact.

Outside-mounted seals are considered to be used for low-pressure applications since both seal faces, the primary ring and mating ring, are put in tension. This limits the pressure capability of the seal. An external seal installation is used to minimize corrosion that might occur if the metal parts of the seal were directly exposed to the liquid being sealed.

Multiple seals are used in applications requiring

- A neutral liquid for lubrication
- Improved corrosion resistance
- A buffered area for plant safety

Double seals consist of two single seals back to back, with the primary rings facing in opposite directions in the seal chamber. The neutral liquid, at a pressure higher than that of the liquid being pumped, lubricates the seal faces (see Figure 14). The inboard seal keeps the liquid being pumped from entering the seal chamber. Both inboard and outboard seals prevent the loss of neutral lubricating liquid.

FIGURE 13 Single seal installations: a) outside mounted, b) inside mounted

FIGURE 14 Double Seals

Double seals can be used in an opposed arrangement. Two seals are mounted face to face, with the primary sealing rings rotating on a common mating ring (see Figure 15). In this case, the neutral liquid is circulated between the seals at a pressure lower than that of the process fluid. This pressure is limited since the outboard seal faces are in tension. The inboard seal is similar to a single inside-mounted seal and carries the full differential pressure of the seal chamber to the neutral liquid. The outboard seal carries only the pressure of the neutral liquid to the atmosphere. The purpose of this arrangement is to fit a seal installation having a shorter axial length than is possible with back-to-back double seals and still form a buffered area for plant safety.

Tandem seals are arranged with two single seals mounted in the same direction (see Figure 16). The outboard seal and neutral liquid create a buffer zone between the liquid being pumped and the atmosphere. Normally, the pressure differential from the liquid

FIGURE 15 Opposed double seals

FIGURE 16 Tandem seals

being sealed and atmosphere is taken across the inboard seal, while the neutral lubricating liquid is at atmosphere pressure. This arrangement can also be used as a method to break down the pressure on high-pressure applications. For example, the pressure difference across each seal can be half the fluid pressure being sealed. The liquid in the outboard seal chamber may be circulated to remove seal heat. Tandem seals are used on toxic or flammable liquids, which require a buffered or safety zone.

Package or cartridge seals are an extension of other seal arrangements. A package seal requires no special measurements prior to seal installation. For a single seal, the seal package consists of the gland plate, sleeve, and drive collar (see Figure 17). A spacer is provided on most package seals to properly set the seal faces. The spacer is removed after the drive collar has been locked to the shaft and the gland plate bolted to the pump.

CLASSIFICATION OF SEALS BY DESIGN

There are four seal classification groups:

- Unbalanced or balanced
- Rotating or stationary seal head

FIGURE 17 A single package (cartridge) seal assembly (John Crane Inc.)

- Single-spring or multiple-spring construction
- Pusher or nonpusher secondary seal design

The selection of an unbalanced or balanced seal is determined by the pressure in the seal chamber. Balance is a way of controlling the contact pressure between the seal faces and power generated by the seal. When the percentage of balance b (the ratio of hydraulic closing area to seal face area) is 100 percent or greater, the seal is referred to as unbalanced. When the percentage of balance for a seal is less than 100 (1.0), the seal is balanced. Figure 18 illustrates common unbalanced and balanced seals.

The selection of a rotating or stationary seal is determined by the speed of the pump shaft. A seal that rotates with the shaft is a rotating seal assembly. Typical rotating seals are shown in Figures 17, 21 and 22. When the mating ring rotates with the shaft, the seal is stationary (see Figure 19). Rotating seal heads are common in the industry for normal pump shaft speeds. As a rule of thumb, when the shaft speed exceeds 5,000 ft/min (25.4 m/s), stationary seals are required. Higher speed applications require a rotating mating ring to keep unbalanced forces, which may result in seal vibration, to a minimum. A stationary seal should be considered for all split case pumps. This will eliminate seal problems that occur when the top and bottom halves of the pump casing do not line up. The pressure in the pump can cause a misalignment of these parts that creates an out-of-square condition at the seal faces.

The selection of a single-spring or multiple-spring seal head construction is determined by the space limits and the liquid sealed. Single-spring seals are most often used with bellows seals to load the seal faces (see Figure 20a). The advantage of this type of construction is that the openness of design makes the spring a nonclogging component of the seal assembly. The coils are made of a large diameter spring wire and therefore can withstand a great deal of corrosion.

Multiple-spring seals require a shorter axial space. Face loading is accomplished by a combination of springs placed about the circumference of the shaft (refer to Figure 1 and see Figure 20b). Most multiple-spring designs are used with assemblies having O-rings or wedges as secondary seals.

Pusher-type seals are defined as seal assemblies in which the secondary seal is moved along the shaft by the mechanical load of the seal and the hydraulic pressure in the seal chamber. The designation applies to seals that use an O-ring, wedge, or V-ring. A typical construction is illustrated in Figure 21.

The primary ring, with a hardened metal surface, rotates with the shaft and is held against the stationary ring by the compression ring through loading of the O-ring. The

FIGURE 18 Common unbalanced and balanced seals

compression ring supports a nest of springs that is connected at the opposite end by a collar, which is fixed to the shaft. The primary ring is flexibly mounted to take up any shaft deflection or equipment vibration. The collar is fixed to the shaft by setscrews.

Another pusher-type seal is illustrated in Figure 22. When elastomers cannot be used in the product, a wedge made of TFE must be considered. A metal retainer locked to the shaft by (A) provides a positive drive through the shaft and to the primary ring (F) through drive dents (D), which fit corresponding grooves. The seal between the primary ring and shaft or sleeve is made by a wedge (E), which is preloaded by multiple springs (B). The spring load is distributed uniformly by a metal disc (C). The primary ring (G) contacts the mating ring (H) to form the dynamic seal.

Pusher seals also come in split designs. Illustrated in Figure 23 is a split seal design for an ANSI pump. This is a fully split seal design with all of the basic parts fitted outside the seal chamber. The gland plate is fully split and provides easy access to other seal components. A finger spring located on the atmospheric side of the seal provides an axial load and drive to the stationary primary ring. Since it is located on the atmospheric side of the seal, it will not be clogged from material in the pumpage. This is suited for a variety of applications, including paper stock, sewage, slurries, and river water. Two flush ports in the gland plate provide for a seal flush for cooling.

FIGURE 19 Stationary seal with a rotating mating ring (John Crane Inc.)

FIGURE 21 O-ring type mechanical seal (Flowserve Corp.)

FIGURE 22 Wedge-type mechanical seal (John Crane Inc.)

FIGURE 23 A split seal design for an ANSI pump (John Crane Inc.)

FIGURE 24 A half-convolution bellows seal (John Crane Inc.)

Nonpusher seals are defined as seal assemblies in which the secondary seal is not forced along the shaft by the mechanical load or hydraulic pressure in the seal chamber. Instead, all movement is taken up by the bellows convolution. This definition applies to those seals that use half-, full-, and multiple-convolution bellows as a secondary seal.

The half-convolution bellows seals are always made of an elastomer (see Figure 24). The tail of the bellows is held to the shaft by a drive band. This squeeze fit seals the shaft and enables the unit to rotate with the shaft. Positive drive is accomplished through the drive band, retainer, and primary ring by a series of slots and dents. A static seal is created at the back of the primary ring and at the front of the bellows. This type of seal is used for light-duty service conditions. The amount of axial travel along the shaft is half that of a full convolution bellows.

The full-convolution bellows seal is illustrated in Figure 25. The tail of the bellows is held to the shaft by a drive band. The squeeze fit seals the shaft and enables the unit to rotate with the shaft. The drive for the seal assembly is similar to that of the half-convolution seal. Static sealing is accomplished at the front of the bellows and the back of the primary ring. The heavier full-convolution bellows design can tolerate greater shaft motion and runout to pressures of 1200 lb/in² (8.3 bar).

Multiple-convolution bellows seals are necessary to add flexibility to those secondary seal materials that cannot be used in any other shape. The mechanical characteristics of TFE and metals require multiple-convolution designs.

FIGURE 25 A full-convolution bellows seal (John Crane Inc.)

A TFE bellows assembly is illustrated in Figure 26. Because of the large cross-sectional area, these types of seals are mounted outside the seal chamber. Pressure at the inside diameter of the seal helps keep the faces closed. Small springs on the atmosphere side of the seal supply the mechanical load to keep the seal faces closed initially.

Multiple convolution metal bellows seals come in various designs and are discussed in the following section.

SEALING REQUIREMENTS IN THE PETROLEUM REFINING INDUSTRY

The API Standard 682 is an industrial standard developed by users with input from equipment and seal manufacturers. The goal of the standard was to create a specification for seals that would have a good probability of meeting emission standards defined by the U.S. Clean Air Act of 1990 and have a life of at least three years. The implementation of this specification indicates not only an increase in emissions control, but also a major increase in equipment reliability.

The following contacting, liquid-lubricated seal designs were identified by API 682, 1st edition (October 1994) as solutions to sealing refinery services. These have been verified by seal manufacturer tests under simulated refinery conditions. These are as follows:

- **Type A** A single, pusher-type seal mounted inside the seal chamber with a rotating flexible element. This is a balanced cartridge design with multiple springs and an O-ring as a secondary seal (see Figure 27). This seal is preferred for all refinery services except non-flashing hydrocarbons above 300°F (150°C). It is considered to be the standard for temperatures up to 500°F (265°C).
- **Type B** A single, low-temperature, non-pusher, inside-mounted seal, with a rotating metal bellows flexible element. The secondary static seals for this nickel alloy metal bellows design are fluorocarbon elastomer O-rings. This low-temperature seal design is a standard optional selection for non-flashing hydrocarbon services up to 300°F (150°C).
- **Type C** A single, high-temperature, non-pusher, inside-mounted seal with a stationary metal bellows flexible element. The secondary static seals for this high-temperature bellows design are flexible graphite. This seal is the standard selection for non-flashing hydrocarbon applications when temperatures are above 300°F (150°C) and pressures are less than 250 lb/in² absolute (17 bar).

Each of the previous seal types is also available as a dual seal arrangement (see Figure 30). When the space between the inboard and outboard seals is pressurized with a barrier fluid, the seal arrangement is referred to as a pressurized dual seal. When the

FIGURE 26 A Teflon bellows seal (John Crane Inc.)

FIGURE 27 Type A Single mounted pusher seal (John Crane Inc.)

FIGURE 28 Type B Single inside mounted non-pusher seal (John Crane Inc.)

FIGURE 29 Type C Single inside mounted high temperature seal (John Crane Inc.)

FIGURE 30 Pressurized dual API 682 seal for HF alkylatin service (John Crane Inc.)

space between the inboard and outboard seals is unpressurized with a buffer fluid, the seal arrangement is referred to as a nonpressurized dual seal. This is the only seal cartridge that can function as a double or tandem seal with the same individual seal parts. The terms *barrier fluid* and *buffer fluid* refer to the same fluid lubricating the seal. When the fluid is pressurized, it is a barrier fluid. When the fluid is non-pressurized, it is a buffer fluid.

FIGURE 31 API 682 qualification test rig (John Crane Inc.)

The dual seal design shown in Figure 30 is without a pumping ring on the outside diameter of the outboard seal. This figure also represents a successful installation on an HF alkylation unit. In this design, isobutane is circulated at a pressure greater than at the pressure at the outside diameter of the inboard seal. The isobutane is then flushed over the inboard seal to keep the hydrofluoric acid away from the inboard seal. Seal life has been significantly increased with this improved sealing technology.

API 682 requires qualification testing for all seal designs by the seal manufacturer. To meet these requirements, seal manufacturers constructed new testing facilities that allow testing at simulated refinery conditions for common process fluids. Figure 31 shows an API qualification test rig with instrumentation installed. Each seal type from each seal application group is required to be tested in four different test fluids that model fluids that model fluids from the application groups. These fluids include water, propane, 20 percent NaOH solution, and mineral oil. Each qualification test for each test fluid consists of three phases:

- a. the dynamic phase at constant temperature, pressure, and speed
- b. the static phase at 0 rpm using the same temperature and pressure as the dynamic phase
- c. the cyclic phase at varying temperatures and pressures, including start-ups and shut-downs. For flashing hydrocarbons, the cyclic test phase includes excursions into vapor and back to liquid.

The seal is expected to perform within the regulated emissions limits after being exposed to qualification testing and upset conditions and demonstrate a capability of at least three years life in service. The result of this effort is not only an improvement in emissions control but also a major improvement in seal reliability. This naturally results in substantially lower life-cycle cost for the user.

The success or failure of a seal installation can often be traced to the selection of the proper piping arrangement. A piping arrangement or plan defines how a seal installation will be cooled or, in some cases, heated. Commonly used systems have been defined by API and are shown in Figure 32.

Performance testing to qualify seal designs to API 682 has resulted in an improved seal flush required for cooling. The mating ring, chamfered at the outside diameter, enables the flow of the flush liquid not only around the circumferential groove, but also directly to the

seal faces for cooling. This design also helps to eliminate any trapped vapor at the seal faces (see Figure 33).

GLAND PLATE CONSTRUCTION

An essential component of any seal installation is the *gland plate*. The purpose of this part is to hold either the mating ring assembly or the seal head assembly, depending on whether the seal head is rotating with the shaft or stationary to the pump casing. It is also a pressure-containing component of the installation. The alignment of one of the sealing surfaces, particularly the mating ring used with a rotating seal assembly and a gland plate bushing, is dependent on the fit of the gland plate to the pump. To ensure the proper installation, the API specification requires a register fit with the inside or outside diameter of the seal chamber. The static seal on the face of the seal chamber must be completely confined. Three basic gland plate constructions are shown in Figure 34:

- A *plain* gland plate is used where seal cooling is provided internally through the pump stuffing box and where the liquid to be sealed is not considered hazardous to the plant environment and will not crystallize or carbonize at the atmospheric side of the seal.
- A *flush* gland plate is used where internal cooling is not available. Here coolant (liquid sealed or liquid from an external source) is directed to the seal faces where the seal heat is generated.
- A *flush-and-quench* gland plate is required on those applications that need direct cooling as well as a quench fluid at the atmospheric side of the seal. The purpose of the quench fluid, which may be a liquid, gas, or steam, is to prevent the buildup of any carbonized or crystallized material along the shaft. When properly applied, a seal quench can increase the life of a seal installation by eliminating the loss of seal flexibility due to hangup. This gland plate can also be used for flush, vent, and drain where seal leakage needs to be controlled. Flammable vapors leaking from the seal can be vented to a flare and burned off, while nonflammable liquid leakage can be directed to a safe sump.

Figure 35 illustrates some restrictive devices used in the gland plate when quench or vent-and-drain connections are used. These bushings can be pressed in place, as in Figure 35a, or allowed to float as in Figures 35b, c, and d. Floating bushings enable closer running clearances with the shaft because such bushings are not restricted at their outside diameter. The bushing shown in Figure 35d is also split to enable the thermal expansion of the shaft. This restrictive bushing is preferred on refinery applications. Small packing rings can also be used for a seal quench, as shown in Figure 35e.

SEAL CHAMBER DESIGN

A critical part of the sealing system is the seal chamber design. The selection of the proper seal chamber can increase the life of the mechanical seal. Changes in pump design have resulted in three chambers, as shown in Figure 36. These are the conventional seal chambers, referred to as the standard bore, the enlarged bore, and the tapered bore. Seal chambers can influence the seal environment through pressure, solids handling, vapor removal, and temperature. A standard bore seal chamber was originally designed for packing and has a restriction at the bottom of the chamber that limits the interchange of fluids between the chamber and pumpage. This seal chamber is dependent on the application of the proper piping plan to remove heat or abrasives.

The enlarged bore is similar to a standard bore, enabling the installation of large seal cross-sections and dual seals. The increased cross-section increases the volume of the liquid for cooling. This seal is also dependent on the proper piping plan to remove heat.

The tapered bore seal chamber has increased radial clearance and the bottom of the chamber is exposed to the impeller. The walls of the chamber promote self-venting during shutdown and self-draining during disassembly. Internal flow within the chamber elimi-

nates the need for external piping for cooling. For some applications, operating at a higher pressure will require an external flush.

NON-CONTACTING GAS LUBRICATED SEALS

The evolution of this sealing concept for pumps has its origin in gas sealing technology developed for gas compressors in the mid-1970s. The development of this technology for

| DESCRIPTION | | COMMENTS |
|---|--|--|
| (a) Throttle Bushing |  <p>Atmos.</p> <p>Seal ID</p> <p>0.0125" (3.17 x 10⁻⁴ m)</p> <p>Radial Clearance</p> | Used on vent and drain designs. Made of non-sparking materials. Meets API specifications. |
| (b) Floating Throttle Bushing |  <p>0.0025" (6.35 x 10⁻⁵ m)</p> <p>Radial Clearance</p> | May be used on quench, vent and drain glands. Spring-loaded to float with shaft. Made of non-sparking materials. Meets API specification. Requires more space than fixed bushing. |
| (c) Floating Bushing |  | Soft packing sized to shaft diameter used on quench. Vent and drain glands. Spring loaded. No adjustments required. Excellent dry run. |
| (d) Split Floating Bushing |  | May be used on quench, vent and drain glands. Spring-loaded to float with shaft. Split carbon bushing to take into account shaft expansion due to temperature preferred for API application. |
| (e) Packing Rings |  | Creates positive seal on quench designs. Requires some adjustment during operation. |

FIGURE 35 Common restrictive devices used with quench, or vent and drain gland plates.

pumps was accelerated in the early 1990s as a way to control emissions. Eliminating the contact between the seal faces while the pump shaft is turning also eliminates the tribological problems of frictional heat and wear. This is no easy task with a liquid present in the pump. Deflections of the seal faces from temperature and pressure must be controlled to very precise levels. Gas, rather than a liquid, must be used as a barrier fluid and one of the seal faces must be designed with a lift mechanism.

A lift mechanism can take the shape of a spiral groove, an L-shaped slot, or a controlled wavy surface. When the shaft turns, pressure builds up in the seal faces, which causes the face separation. The basic construction of a spiral groove face and the pressure buildup is shown in Figure 37. The separation of the face is very small and could be measured in nanometers, which enables a small amount of gas to flow across the seal face. Since this type of seal is non-contacting, the only heat that is developed is from the shearing of gas at the seal faces. The small amount of gas flow helps cool the seal faces. The temperature rise at the seal faces is just a few degrees, making this a preferred seal for heat-sensitive liquids. The processes occurring at the seal faces are shown in Figure 38.

The operating envelope for a non-contacting, gas-lubricated seal for liquid pumping services is shown in Figure 39. Since the rubbing contact at the seal faces has been elim-

FIGURE 36 Standard bore, enlarged bore, and tapered bore seal chamber arrangements.

FIGURE 37 Spiral groove seal face and pressure build up in the grooves (John Crane Inc.)

inated, the seal can be operated at the vapor pressure of the liquid being sealed. In addition, no limiting factor exists due to the pressure-velocity relationship and wear at the seal faces. The limiting factor in the application of the seal is the pressure that has an effect on seal face deflection.

Dual pressurized, gas-lubricated seals have been designed to fit oversized and small bore seal chambers. An oversized seal chamber that enables a larger cross-section seal and that can handle pressures up to 600 psig (40 bar) is illustrated in Figure 40. Many existing pumps in the field have small bore seal chambers and do not require the same pressure capability as a larger cross-section seal. The seal to fit these units is illustrated in Figure 41. This type of seal is being used to pressures of 230 psig (16 bar).

Dual seals are pressurized with an inert gas. Gas pressure is normally 20 to 30 psig (1.4 to 2 bar) above the process liquid being sealed. The amount of gas consumed through a dual seal can be estimated from Figure 42. The gas consumption is the sum of the flow across the inboard and outboard seals. The amount of gas consumed on an annual basis is very small. This makes this type of installation very economical when compared to a fully pressurized liquid barrier/buffer system. Gas pressure and flow are monitored by a safety gas panel like that shown in Figure 43.

This technology represents a solution for those sealing problems that affect the cooling and lubrication of a contacting seal by the liquid being sealed. These problems, identified

FIGURE 38 The processes occurring at the seal faces

FIGURE 39 The operating envelope for a non-contacting, gas-lubricated seal for liquid pumping services. (John Crane Inc.)

by users as reasons for a short seal life, include a loss of seal flush, dry running, startup without venting, *low net positive suction head* (NPSH), and cavitation. Cavitation may also result in vibration of the equipment. The vibration limit for a non-contacting gas lubricated seal is 0.4 in/s (10 mm/s). The benefits of this technology are increased performance, emissions control, safety, reliability, and efficiency for a conventional pump fitted

FIGURE 40 Non-contacting gas-lubricated seal for pumps with a large bore seal chamber (John Crane Inc.)

FIGURE 41 Non-contacting gas-lubricated seal for pumps with a small cross-section seal chamber (John Crane Inc.)

FIGURE 42 Gas consumption through a seal face. (John Crane Inc.)

with non-contacting gas lubricated seals. This translates into increased *mean time between maintenance* (MTBM) and reduced costs of ownership of the equipment. An inert gas, such as nitrogen, is a preferred barrier fluid in refinery and petrochemical industries, while purified air is used in the pharmaceutical and biotech industries. Protecting the environment is the main reason for the development of this technology, but, it is also a primary sealing system used to maintain product purity in the pharmaceutical and biotech industries.

Pumping liquid near its vapor pressure represents a challenge to equipment manufacturers and plant operators. Trying to seal this type of application with a contacting seal will result in an inefficient installation. The amount of heat generated would require too much cooling to prevent the liquid from flashing. The only solution is to eliminate the heat generated at the seal faces, allowing the liquid being sealed to flash to a gas and use a non-contacting gas lubricated seal.

For those liquids that are dangerous to the environment, a tandem seal arrangement would be used. The space between the seals would be vented to a flair or vapor disposal

FIGURE 43 A safety gas panel for monitoring gas pressure and flow (John Crane Inc.)

FIGURE 44 Early non-contacting gas-lubricated seal design for vaporizing hydrocarbon service (John Crane Inc.)

TABLE 2 Typical vaporizing hydrocarbon services (John Crane Inc.)

| Operating Condition/ Seal Size (in) | Liquid | Pressure (lb/in ²) | Temperature (Degree F) Min/Max | Speed (rpm) |
|--|--------|-----------------------------------|-----------------------------------|----------------|
| 1.250 | Ethane | 554 | +45 / +125 | 3,560 |
| 1.875 | LNG | 327 | +37 / +125 | 3,560 |
| 2.875 | LNG | 400 | +30 / +125 | 3,560 |
| 3.375 | Ethane | 392 | -49 / +125 | 1,750 |
| 5.250 | LNG | 850 | +30 / +125 | 3,560 |

area. Figure 44 represents an early tandem seal arrangement for this type of service. Applying this technology to pumps has resulted in a significant increase in equipment reliability. A list of typical applications for non-contacting gas seals to be applied to vaporizing hydrocarbon liquid services is shown in Table 2.

FIGURE 45 A non-contacting gas-lubricated seal for cryogenic service (John Crane Inc.)

Cryogenic liquids represent a similar design challenge in sealing technology. Traditionally, pumps that are used to pump these liquids relied on contacting seal designs. Although these fluids were at cryogenic temperatures, the seals were operating near the boiling point of the liquid. Frictional heat was enough to vaporize or flash the liquid to a gas. This resulted in short seal life. By allowing the liquid to flash to a gas and by using non-contacting gas lubricated seals, seal life has been extended from weeks to years. A non-contacting gas lubricated cryogenic seal is illustrated in Figure 45. Due to the low temperatures involved, a metal bellows is required in the seal design.

MATERIALS OF CONSTRUCTION

All component parts of a seal are selected based on their corrosion resistance to the liquid being sealed. The *National Association of Corrosion Engineers* (NACE) Corrosion Handbook provides corrosion rates for many materials of construction for mechanical seals used with a variety of liquids and gases. When the corrosion rate is greater than two mils (0.05 mm) per year, double seals that keep the hardware items of the seal in a neutral liquid should be selected to reduce corrosion. In this design, only the inside diameter of the mating ring, the primary ring, and the secondary seal are exposed to the corrosive liquid and should be constructed of corrosion-resistant materials, such as ceramic, carbon, and Teflon. Common materials of construction are given in Table 3. Table 4 lists the properties of common seal face materials.

The operating temperature is a primary consideration in the design of the secondary and static seals in the assembly. These parts must retain their flexibility throughout the life of the seal, as flexibility is necessary to retain the liquid at the secondary seal as well as to enable a degree of freedom for the primary ring to follow the mating ring. The usable temperature limits for common secondary and static seal materials are given in Table 5.

An additional consideration in the selection of the primary and mating ring materials in sliding contact is their *PV* limitation. This value is an indication of how well the material combination will resist adhesive wear, which is the dominant wear in mechanical seals. Limiting *PV* values for various face combinations are given in Table 6. Each limiting value has been developed for a wear rate that provides an equivalent seal life of two years. A *PV* value for an individual application can be compared with the limiting *PV*

TABLE 3 Common materials of construction for mechanical seals

| Components | Materials of Construction |
|--|--|
| Secondary Seals: | |
| O-rings | Nitrile, Ethylene Propylene, Chloroprene, Fluoroelastomer, Perfluoroelastomer |
| Bellows | Nitrile, Ethylene Propylene, Chloroprene, Fluoroelastomer |
| Wedge or U Cups | Fluorocarbon |
| Metal Bellows | Stainless steel, Nickel-base Alloy |
| Primary Ring | Carbon, Metal-filled Carbon, Tungsten Carbide, Silicon Carbide, Siliconized Carbon, Bronze |
| Hardware (retainer, disc, snap rings, set screws, springs) | Stainless Steel, Nickel-base Alloy |
| Mating Ring | Ceramic, Cast Iron, Tungsten Carbide, Silicon Carbide |

value for the materials used to determine satisfactory service. These values apply to aqueous solutions at 120°F (49°C). For lubricating liquids such as oil, values of 60 percent or higher can be used. Higher or lower values of *PV* may apply, depending on the seal face design.

INSTALLING THE SEAL AND IDENTIFYING CAUSES OF SEAL LEAKAGE _____

A successful seal installation requires operation of the pump within the manufacturer's specification. Relative movement between the seal parts or shaft sleeve usually indicates that mechanical motion has been transmitted to the seal parts from misalignment (angular or parallel), endplay, or radial runout of the pump (see Figure 46).

Angular misalignment results when the mating ring is not square with the shaft and will cause excessive movement of internal seal parts as the primary ring follows the out-of-square mating ring. This movement will fret the sleeve or seal hardware on pusher type seal designs. Angular misalignment may also occur from a seal chamber that has been distorted by piping strain developed at operating temperatures. Damage in the wearing rings can also be found here if the pump seal chamber has been distorted.

Parallel misalignment results when the seal chamber is not properly aligned with the rest of the pump. No seal problems will occur unless the shaft strikes the inside diameter of the mating ring. If damage has occurred, there will also be damage to the bushing at the bottom of the seal chamber at the same location as the mating ring.

Excessive axial endplay can damage the seal surfaces and cause fretting. If the seal is continually being loaded and unloaded, abrasives can penetrate the seal faces and cause premature wear of the primary and mating rings. Thermal damage in the form of heat checking in the seal faces because of excessive endplay can occur if the seal is operated below working height.

Radial runout in excess of limits established by the pump manufacturer could cause excessive vibration at the seal. This vibration, coupled with small amounts of the other types of motion that have been defined, will shorten seal life.

Instructions and seal drawings should be reviewed to determine the installation dimension or spacing required to ensure that the seal is at its proper working height (see Figure 47). The installation reference can be determined by locating the face of the seal chamber on the surface of the sleeve and then measuring along the sleeve after it has been

TABLE 4 Typical properties of common seal face material

TABLE 5 Temperature limits of secondary seal materials

removed from the unit. It is not necessary to use this procedure if a step in the sleeve or collar has been designed into the assembly to provide for proper seal setting. Assembling other parts of the seal will bring the unit to its correct working height.

All package or cartridge shaft seals can be assembled with relative ease because just the bolts at the gland plate and set screws on the drive collar need to be fastened to the seal chamber and shaft. After the seal spacer is removed, the unit is ready to operate.

To assemble a mechanical seal to a pump, a spacer coupling is required. If the pump is packed but may later be converted to mechanical seals, a spacer coupling should be included in the pump design.

Since a seal has precision-lapped faces and because secondary seal surfaces are critical in the assembly, installations to the equipment should be kept as clean as possible. All lead edges on sleeves and glands should have sufficient chamfers to facilitate installation.

When mechanical seals are properly applied, there should be no static leakage and, under normal conditions, the amount of dynamic leakage should range from none to just a few drops per minute. Under a full vacuum, a mechanical seal is used to prevent air from leaking into the pump. If excessive leakage occurs, the cause must be identified and corrected. Causes for seal leakage with possible corrections are listed in Table 7. In addition, Figure 48 illustrates the most common causes for mechanical seal leakage. Further information on seal leakage and the related condition of seal parts can be found in the works listed in the "Further Reading" section.

TABLE 6 Frequently used seal face materials and their *PV* limitations

| Sliding Materials | | PV limit, lb/in ² · ft/min (bar · m/s) | Comments |
|---|--|---|--|
| Rotating | Stationary | | |
| Carbon-graphite | Ni-resist | 100,000 (35.03) | Better thermal shock resistance than ceramic |
| | Ceramic (85% Al ₂ O ₃) | 100,000 (35.03) | Poor thermal shock resistance and much better corrosion resistance than Ni-resist |
| | Ceramic (99% Al ₂ O ₃) | 100,000 (35.03) | Better corrosion resistance than 85% Al ₂ O ₃ Ceramic |
| | Tungsten Carbide (6% Co) | 500,000 (175.15) | With bronze-filled carbon graphite, PV is up to 100,000 lb/in ² ft/min (35.02 bar · m/s) |
| | Tungsten Carbide (6% Ni) | 500,000 (175.15) | Ni binder for better corrosion resistance |
| | Silicon Carbide (converted Carbon) | 500,000 (175.15) | Good wear resistance; thin layer of SiC makes relapping questionable |
| | Silicon Carbide (solid) | 500,000 (175.15) | Better corrosion resistance than Tungsten Carbide but poorer thermal shock resistance |
| Carbon-graphite | | 500,000 (17.51) | Low PV, but very good against face blistering |
| Ceramic | | 10,000 (3.50) | Good service on sealing paint pigments |
| Tungsten Carbide | | 120,000 (42.04) | PV is up to 185,000 lb/in ² ft/min (64.8 bar · m/s) with two grades that have different % of binder |
| Tungsten Carbide/ Silicon Carbide (solid) | | 300,000 (105.1) | Excellent abrasion resistance. Commonly used on high temperature applications |
| Silicon Carbide (converted carbon) | | 500,000 (175.15) | Excellent abrasion resistance, more economical than solid Silicon Carbide |
| Silicon Carbide (solid) | | 350,000 (122.6) | Excellent abrasion resistance, good corrosion resistance and moderate thermal shock resistance |

FIGURE 46 Common types of motion that influence seal performance

TABLE 7 Checklist for identifying causes of seal leakage

| Symptom | Possible Causes | Corrective procedures | |
|---|--|--|---|
| Seal spits and sputters ("face popping") in operation | Seal fluid vaporizing at seal interfaces | Increase cooling of seal faces. | |
| | | Check for proper seal balance with seal manufacturer | |
| | | Add bypass flush line if not in use | |
| | | Enlarge bypass flush line and/or orifices in gland plate | |
| | | Check for seal interface cooling with seal manufacturer | |
| Seal drips steadily | Faces not flat Carbon graphite seal faces blistered Seal faces thermally distorted | Check for incorrect installation dimensions | |
| | | Check for improper materials or seals for the application | |
| | | Improve cooling flush lines | |
| | | Check for gland plate distortion due to overtightening of gland bolts | |
| | | Check gland gasket for proper compression | |
| | | Clean out foreign particles between seal faces; relap faces if necessary | |
| | | Check for cracks and chips at seal faces; replace primary and mating rings | |
| | Secondary seals nicked or scratched during installation O-rings overaged Secondary seals hard and brittle from compression set Secondary seals soft and sticky from chemical attack | Replace secondary seals | |
| | | Check for proper lead-in chamfers, burrs, and so on | |
| | | Check for proper seals with seal manufacturer | |
| | | Check with seal manufacturer for other material | |
| | | Spring failure Hardware damaged by erosion Drive mechanisms corroded | Replace parts |
| | | | Check with seal manufacturer for other material |

(continues)

TABLE 7 Continued.

| Symptom | Possible Causes | Corrective procedures |
|---|---|--|
| Seal squeals during operation | Amount of liquid inadequate to lubricate seal faces | Add bypass flush line if not in use Enlarge bypass flush line and/or orifices in gland plate |
| Carbon dust accumulates on outside of gland ring. | Amount of liquid inadequate to lubricate seal faces Liquid film evaporating between seal faces | Add bypass flush line if not in use Enlarge bypass flush line and/or orifices in gland plate Check for proper seal design with seal manufacturer if pressure in stuffing box is excessively high |
| Seal leaks | Nothing appears to be wrong | Refer to list under “Seal drips steadily” Check for squareness of stuffing box to shaft Align shaft, impeller, bearing, and so on to prevent shaft vibration and/or distortion of gland plate and/or mating ring |
| Seal life is short. | Abrasive fluid | Prevent abrasives from accumulating at seal faces Add bypass flush line if not in use Use abrasive separator or filter |
| | Seal running too hot | Increase cooling of seal faces Increase bypass flush line flow Check for obstructed flow in cooling lines |
| | Equipment mechanically out of line | Align Check for rubbing of seal on shaft |

1. FULL CONTACT PATTERN

**OBSERVATION:**

Typical contact pattern for a non-leaking seal. Full contact on the mating ring surface through 360°. Little or no measurable wear on either seal ring. If leakage is present with this type face pattern, the secondary seals must be examined.

2. CONING (NEGATIVE ROTATION)

**OBSERVATION:**

Heavy contact on the mating ring pattern at the outside diameter of the seal. Fades away to no visible contact at the inside diameter of contact pattern. Possible edge chipping on the outside diameter of primary ring.

3. THERMAL DISTORTION (POSITIVE ROTATION)

**OBSERVATION:**

Heavy contact on the mating ring pattern at the inside diameter of the seal. Fades away to no visible contact at the outside diameter of contact pattern. Possible edge chipping on the inside diameter of the primary ring.

4. MECHANICAL DISTORTION

**OBSERVATION:**

Mating ring is distorted mechanically, creating two large contact spots. Pattern fades away between contact areas.

5. MECHANICAL DISTORTION

**OBSERVATION:**

Mating ring is being distorted mechanically, creating contact through approximately 270°. Pattern fades away at the low spot.

6. MECHANICAL DISTORTION

**OBSERVATION:**

Mating ring is being distorted mechanically, creating contact at both. High spots are at each port location.

FIGURE 48 Identifying causes of seal leakage (John Crane Inc.)

7. HIGH WEAR OR THERMALLY DISTRESSED SURFACE

OBSERVATION:

High wear of mating or thermally distressed surface (heat cracking) through 360°. High primary ring wear with carbon deposits on atmosphere side of seal. Possible edge chipping of primary ring due to opening and closing of seal faces.

8. SECTION OF THERMALLY DISTRESSED SURFACE

OBSERVATION:

Thermally distressed area approximately 1/3 of the contact pattern. Distressed area 180° from inlet of seal fluid. High primary ring wear with possible carbon deposits on atmosphere side of seal.

9. PATCHES OF THERMALLY DISTRESSED SURFACE

OBSERVATION:

Patches of thermally distressed surface (heat cracking). 2, 3, 4, 5 or 6 hot spots are possible. High primary ring wear with possible carbon deposits on atmosphere side of seal. Failure due to hot spots (thermal asperities); is likely to occur on light specific gravity liquids at high speeds and pressures.

10. HIGH WEAR AND GROOVING

OBSERVATION:

High wear of the mating ring. Primary ring has grooved the mating ring evenly through 360°.

11. OUT-OF-SQUARE MATING RING

OBSERVATION:

Contact pattern through 360° slightly larger than primary ring face width. High spot may be present on the mating ring opposite a drive pin hole. Mating ring without static seals will rock or move in gland plate or holder.

12. WIDE CONTACT PATTERN

OBSERVATION:

Contact pattern considerably wider on the mating ring than the face width of the primary ring.

2.2.4

CENTRIFUGAL PUMP INJECTION-TYPE SHAFT SEALS

ROBERT D. ASHTON
TIMOTHY L. WOTRING

Injection-type shaft seals (sometimes called *packless stuffing boxes*) are designed to control leakage from hot-water pumps. Cool water is injected into each seal to either suppress or regulate the hot leakage, which would otherwise flash upon reaching the outside of the pump.

Injection-type shaft seals provide high reliability and yet require little maintenance. They are used primarily in power plant boiler-feed and reactor-feed pump applications where shaft peripheral speeds are high (3600 rpm and up) and pumping temperatures are greater than 250°F (120°C). Under these conditions, conventional packing or mechanical-seal-type stuffing boxes may not be suitable or desirable.

Injection shaft seals are either *serrated throttle bushings* or *floating ring seal* designs that regulate the flow, temperature, and pressure of the controlled leakage. The flow of the cool injection and of any hot water in the seals depends on operating pressures, but it is restricted by close seal clearances and is regulated by injection control valves.

The operating temperature of the seals is controlled by allowing cool injection water to surround the outside of the seal. Ports in the seal enable the cool injection water access to the shaft to either overcome or mix with hot water in the seal so that the resulting seal leakage is cool.

The seal designs must provide sufficient pressure breakdown between the pump suction or balance device chamber pressures inside the pump and the atmospheric conditions outside the pump. Upon reaching the outside of the seal, the cool leakage is piped away by gravity drain for eventual return to the power plant feedwater system.

SERRATED THROTTLE BUSHINGS

The construction of a serrated (sometimes called *labyrinth* or *grooved*) bushing (see Figure 1) varies from one pump manufacturer to another. However, the serrated designs basically involve a rotating shaft running with a reasonably small clearance, such as 0.002 to

FIGURE 1 ***Author: Replacement caption was not provided***

0.003 in per inch (0.002 to 0.003 mm per millimeter) of the shaft diameter within a solid stainless steel (typically 12 percent chrome) stationary bushing installed in the pump casing end cover. Grooved serrations are applied to the hardened stainless steel rotating surface (usually a shaft sleeve) or to the stationary bushing or to both rotating and stationary surfaces to effect a high throttling action or stuffing box leakage reduction.

The serrations create a more effective pressure breakdown than a smooth axial surface and enable increased running clearances to let foreign particles, such as grit, pass through or flush out in the grooves. The increased clearances also enable more tolerance for any displacement between rotating and stationary components that might result from assembly misalignment or from distortions induced by transient temperatures. The grooved running surface area at clearances is greatly reduced relative to that of a smooth axial surface, and therefore possible metal surface contact between rotating and stationary parts is reduced during transient operations.

Seal leakage could be reduced by decreasing the running clearance in the injection seal, but the smaller clearance would limit the capability of the serrated seal to conform to radial shaft movement. Reduced clearances in any injection seal design may lead to problems with thermal distortions caused by a loss of available cool injection water and may also increase galling by particles trapped in the seal running fits.

FLOATING RING DESIGN

A segmented throttle bushing made of many floating rings will enable conformity with the radial shaft movement and smaller running clearances to reduce seal leakage. The construction of a floating ring stuffing box (see Figure 2) varies from one pump manufacturer

FIGURE 2 Floating ring seal design with shaft sleeve. Pegs prevent rotation of spring-loaded rings but let them float radially. (From *Power*, August 1980, McGraw-Hill, New York, copyright 1980)

to another, but the unit basically consists of a stack of hardened, martensitic stainless steel rings (typically 17 percent chrome), instead of a stationary bushing. The rings run against a smooth, hardened, martensitic stainless steel (typically 12 to 17 percent chrome) rotating shaft sleeve surface.

The separate rings are all contained within a housing installed in the pump casing end cover. Each ring is loaded against an adjacent stainless steel ring spacer so that a stationary seal is produced in the axial direction, but the ring is still able to move radially with the shaft. An axial loading of the rings is provided by hydraulic pressure during operation and by springs during idle pump periods. The rings are locked against rotation usually by pegs and/or a slot arrangement.

A small radial clearance, usually 0.001 to 0.0015 in per inch (0.001 0.0015 mm per mm) of the shaft diameter, is provided between the rings and the shaft sleeve to provide an adequate throttling of seal leakage across the limited number of seal rings. The length of each ring varies with the diameter of the injection-type seal but is generally about 0.50 in (13 mm). The radial clearance enables a reduced injection flow but increases the sensitivity of the seal to foreign particles in the seal leakage.

The individual seal rings are permitted to move radially (float), finding an equilibrium running position relative to the shaft. The capability to float up to .016 in (.4 mm) radially increases the tolerance for shaft misalignment as the shaft passes through the seal area. The multiplicity of seal rings further reduces the effect of any angular displacement between the rotating and stationary components that might arise from errors in the original assembly or from distortions caused by temperature changes during pump load variations.

Some injection-type shaft seal designs use a combination of serrations and floating rings in the same stuffing box. For either type of seal, careful maintenance during the assembly or disassembly requires accurate alignment of the rotating and stationary components as well as careful handling to avoid scratching the components. Cleanliness is of utmost importance with shaft seals.

CONDENSATE INJECTION REQUIREMENTS

Because boiler-feed and reactor-feed pumps normally have high feedwater temperatures, 250 to 500°F (120 to 260°C), with consequent vapor pressures higher than external atmospheric conditions, the seal leakage must be cooled to avoid flashing in the stuffing box or outside the pump. This cooling is usually accomplished by injecting cold condensate from a power plant condensate pump directly into the seal to cool the stuffing box components as well as the seal leakage.

The amount of condensate injection water required will depend on several factors, including (1) whether the design is a serrated or floating ring, (2) the type of seal control

system, (3) the diameter, clearance, and rotating speed of the running fit, and (4) the internal pump pressure and temperature. A typical example of stuffing box flows would be a 5500-rpm, boiler-feed pump with a temperature-controlled seal system (described later) and a serrated 5-in (127-mm) diameter running seal with about 0.015 inches (0.38 mm) of diametrical clearance. The approximate flows would be as follows:

1. Total injection per seal: 5 to 15 gpm (0.3 to 1.0 l/s)
2. Leakage from internal pump to seal: 0 to 5 gpm (0 to 0.3 l/s)
3. Drainage from each seal: 8 to 20 gpm (0.5 to 1.3 l/s)

Given a seal with a floating ring design (having typically half the clearance of seals with a serrated bushing design), the previous conditions would require only 50 to 60 percent of the injection water needed by the serrated bushing design with the larger clearance.

During pump standby periods, higher injection and leakage flows are required because of reduced seal throttling caused by low or zero speed, by high internal pump pressures, or by a pump balance device that induces higher internal leakage during standby. The injection flows to both stuffing boxes on a multistage pump may not be the same as a result of pump balance action at one end of the pump.

Cold condensate, 85 to 110°F (30 to 45°C), is usually available from the power plant condensate pump or secondary condensate booster pump discharge. The variation in condensate supply pressure relative to internal boiler-feed pump pressure makes it necessary to use injection control systems for satisfactory seal operation.

Condensate injection systems vary to accommodate the wide range of pressures and temperatures found in different power plant feedwater system layouts. The four basic types of injection flow systems are (1) manual, (2) differential pressure-controlled, (3) differential temperature-controlled, and (4) constant drain temperature control.

Manual System Manual flow control requires setting and readjusting a valve by hand for each stuffing box each time a change occurs in pump operating conditions due to varying plant loads. Although it is possible to use such a control system, it is not usually recommended because of the inability to automatically compensate for rapid changing conditions.

Differential Pressure-Controlled System The differential pressure-controlled shaft seals operate as cold condensate maintained at a pressure greater than boiler-feed pump suction is injected into the central portion of the seal. By maintaining an injection pressure above the pump seal chamber pressure, a small portion of this injection water flows into the pump proper, and most of the injected water flows out of the seal into a collection chamber adjacent to the pump bearing bracket. The leakage in the collection chamber, which is vented to the atmosphere, is drained by gravity for an eventual return to the main feedwater system.

The differential pressure-controlled system has a pneumatic injection control valve. This valve in the condensate injection line is governed by an air signal received from a differential pressure control monitor that maintains the preset pressure differential, 10 to 25 lb/in² (70 to 170 kN/m²), between the injection pressure and the internal pump pressure. This system is not always favored, however, because of a feedback instability tendency resulting from operating pressure changes affecting the valve position, which changes pressure, and so on. Another unfavorable factor for hot-water service is the introduction of cold condensate into a hot pump at all times, including pump idle periods, affecting pump prewarming conditions.

Differential Temperature-Controlled System The differential temperature-controlled system operates by maintaining a seal drain temperature differential of 25°F (14°C) above the injection water temperature. The temperature differential ensures a continuous out-leakage of hot boiler feed water. The hot out-leakage is desirable, ensuring that cold water cannot be injected into the pump and thus eliminating thermal distortions that occur with the differential pressure-controlled system. The valve controllers are identical to the controllers used for the differential pressure-controlled system.

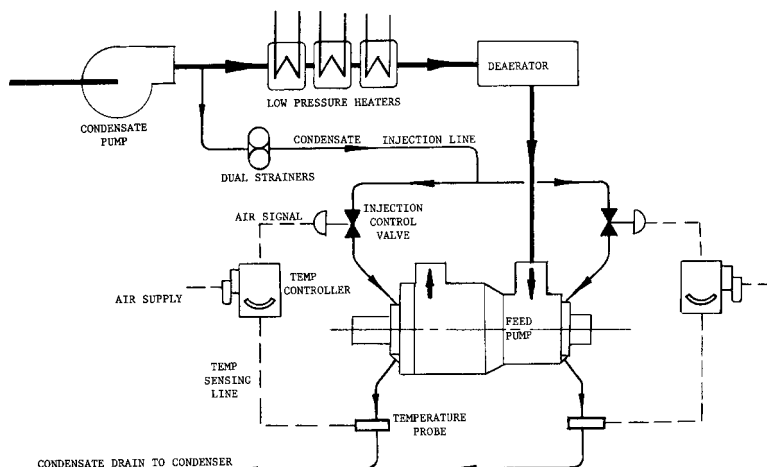

FIGURE 3 Temperature-controlled system regulating condensate injection to feed pump shaft seals

Constant Drain Temperature-Controlled System The constant drain temperature-controlled seal system (see Figure 3) controls hot out-leakage by throttling the injection flow to maintain a preset seal drain temperature. This system has a temperature-sensing probe in each seal drain line. Each probe is connected to an indicating temperature controller, which provides an air signal to a pneumatic control valve in the condensate injection line for control of the seal injection flow rate. Electronic control systems are often used where thermocouples or RTD's sense drain temperatures. The signal output is then processed through an I/P controller that adjusts the position of the pneumatically operated throttle valve as required.

The cold condensate is injected into the stuffing box central portion and allowed to mix with hot water entering the seal from inside the pump. The drain temperature is maintained at a preset 140 to 150°F (60 to 66°C) to preclude flashing in the stuffing box or in the drains. Note that with this system some hot water enters the seal. Therefore, cold condensate does *not* enter the hot pump and does not adversely affect pump warming conditions, especially during extended idle periods. The required condensate injection pressure is at least equal to the internal stuffing box pressure plus interim frictional loss between the condensate supply source and the point of hot-water mixture. Note that this system *may* enable satisfactory operation even when the condensate supply pressure is nearly equal to boiler-feed pump suction pressure. In addition to providing a rapid response to variations in operating pump conditions, this type of control will always supply just enough injection water to maintain the recommended drainage temperature.

Intermediate Leakoff System The intermediate-leakoff shaft seal system (see Figure 4) has many variations but basically uses a bleedoff from a central portion of the stuffing box. This system may be used to reduce internal stuffing box pressure if high boiler-feed pump suction pressure exists. To create a positive leakoff flow, the intermediate bleedoff flow is piped back to a plant feedwater system low-pressure point, such as a plant condenser, heater, or booster pump suction where the pressure is less than the boiler-feed pump suction pressure. However, the back pressure of the leakoff destination must be above the bleedoff vapor pressure to suppress flashing in the leakoff lines. This back pressure may be the leakoff destination pressure or may be created by an orifice or a valve.

Cold condensate injection into the stuffing box is controlled by a pressure differential monitor maintaining a preset pressure above the bleedoff pressure (refer to Figure 4). A

FIGURE 4 Typical intermediate-leakoff shaft seal system. (From *Power*, September 1980, McGraw-Hill, New York, copyright 1980)

stuffing box drain temperature control can also be used. Note that the cold condensate injection pressure need not equal or overcome a high feed pump suction pressure. The condensate injection temperature must still be 85 to 110°F (30 to 45°C) to keep the drain temperature below the flashing condition. Condensate injection shaft seals without an intermediate bleedoff but that are subject to suction pressures in excess of about 250 lb/in² (1725 kN/m²) must be extremely long for a proper pressure breakdown. Longer shaft seals require thicker pump case end covers, affecting pump cost, and a longer rotating element, which could adversely affect rotor dynamics. The intermediate-leakoff shaft seal is effective where there is high feed pump suction pressure imposed by boiler-feed booster pumps or in a closed feedwater system with no deaerating open heater, wherein a condensate pump discharge can be fully imposed on the feed pump at low plant loads.

In plant systems with feedwater heaters between a booster pump and a feed pump, a high pressure condensate from the cooler booster pump is injected into the seal to enable a cooler intermediate leakoff to help prevent flashing (refer to Figure 2).

INJECTION SOURCES

Many power plant feedwater systems with deaerating direct-contact heaters (open cycle) usually have the boiler-feed pump drawing water directly from the deaerator. These open cycles with constant-speed condensate pumps always have cold condensate supply pressures in excess of boiler-feed pump suction pressure because of the increased available condensate pump head at low system flows and the interim system frictional loss at high system flows.

If a boiler-feed booster pump or a closed feedwater system with no open heaters and resultant higher boiler-feed pump suction pressures is used, the pump manufacturer may elect to require condensate injection seal water booster pumps or may use an intermediate-leakoff packless shaft seal with a condensate injection overcoming only the intermediate leakoff pressure. If the condensate pumps are variable-speed units that enable the condensate injection pressure to drop to an equal feed pump suction pressure at low loads with little or no feedwater system frictional drop, then condensate injection seal water pumps are required. In this situation, at least one pump manufacturer offers an optional pumping

ring configuration in their packless seal that can increase the seal water pressure in the stuffing box to overcome any pump suction pressure.

AUXILIARY EQUIPMENT

The condensate injection piping should be conservatively sized based on the maximum injection flow requirements to obtain a low pressure drop between the injection source and the seal injection control valve. These control valves may be equipped with limit stops to prevent full closure and enable a continuous cool injection to the seals under almost all operating conditions. In some installations, isolating lines are furnished around the valves to enable a continued injection flow even during control valve maintenance. The valves can also be designed to remain open during a failure, such as a loss of station air to the pneumatic controls, and to close only with an air supply. Injection control systems that are not properly maintained might result in cold water entering a hot pump. Should this problem occur while a boiler feed pump is in the hot standby mode or when turning gears, thermal gradients will occur, leading to contact among the close running fits within the pump. Proper maintenance and operation of the injection control systems is necessary to ensure reliable operation of the pump itself. The air supply filter regulators for each control must be furnished with relatively dry clean air at station supply pressure.

The condensate injection supply to the seals must be clear and free of foreign matter to prevent damage to stuffing box components. It is therefore necessary to install filters in the injection line prior to the control valve. To keep damaging fine mill scale, oxide particles, abrasives, and other materials from entering the small seal clearances, several pump manufacturers recommend 100-mesh (150-micron) dual strainers. If dual strainers with isolating valves are used, each filter can be cleaned without interrupting injection flow during pump operation. Pressure gages should be installed before and after each filter to permit the operator to monitor filter pressure drop. A differential pressure switch and alarm for each filter are preferable to alert the operator to clean the strainer when pressure drop becomes excessive.

The condensate injection shaft seals should always be filled with cool water before and during pump operation, even during reverse pump rotation. Some pump manufacturers stipulate that condensate injection *must* be continuous without any interruption during all operation modes.

The clearances in the condensate injection shaft seal may double over the service life of the internal wearing parts. With double clearances, the leakage will approximately double. This factor should be considered when sizing the return drain piping back to the plant condenser if frictional losses are to be kept to a minimum. The drain line should be pitched at least a quarter-inch per foot (20 mm per meter). The collecting chamber at the pump stuffing box is vented to the atmosphere, and the only head available to evacuate the chamber is the static head between the pump and the point of return. This head must always be well in excess of the frictional losses (even after the leakage is doubled). Otherwise, the drains may back up, the collection chambers may overflow, and the adjacent bearing brackets may flood, with subsequent possible intrusion of water into the pump bearings and lubricating oil.

The seal collection chambers have especially large connections to assure proper drainage, provided no back pressure exists. Two types of condensate drain systems can be used to dispose of the drain coming from the collecting seal chambers. One system uses traps that are piped directly to the plant condenser if sufficient static head exists for positive drain flow. The second system collects the drain in a condensate storage tank into which various other drains (from other pumps shaft seals and so on) are also directed. As this vented storage tank is under atmospheric pressure, it must be set at a reasonable elevation below the pump centerline so that the static elevation difference will overcome frictional losses in the drain piping. A separate condensate transfer pump, under control of the storage tank liquid level control system, can then pump the condensate drains from the storage tank into the plant condenser. The storage tank should have its own overflow

protection system that enables outside drainage if, for some reason, proper drainage cannot be achieved. For example, the top of the tank vent pipe should be below the pump centerline to help preclude the possibility of drainage backing up to the level of the pump seal collection chambers. Note that this storage tank should also be large enough for an adequate drainage collection to help prevent backups.

PACKLESS SHAFT SEALS WITHOUT INJECTION

The packless shaft seals that have been so successfully applied to boiler-feed, reactor-feed, and booster pump services are applicable to a number of other services. For instance, they are very suitable for cold-water condensate booster pumps and for high-pressure pumps applied to hydraulic descaling or hydraulic press work. In such services, there is no need to bring in an injection supply water to the breakdown seals (unless the pumped water is not clear and free of gritty material), because the water handled by the pump is already cold with no danger of flashing as it leaves the pump stuffing boxes.

2.2.5 CENTRIFUGAL PUMP OIL FILM JOURNAL BEARINGS

WILBUR SHAPIRO

PRINCIPLES OF OPERATION

A journal bearing is essentially a viscous pump, and it derives load capacity by pumping the lubricant through a small clearance region. In Figure 1, the fluid is dragged along by

FIGURE 1 Two-groove cylindrical bearing.

the rotating journal. To generate pressure, the resistance to pumping must increase in the direction of the flow. In the figure, the journal moves to form a converging tapered clearance in the direction of the rotation or flow.

The eccentricity e is the total displacement of the journal from its concentric position. The attitude angle γ in Figure 1 is the angle between the load direction and the line of centers. Note that, because of the necessity to form a converging wedge, the displacement of the journal is not along a line that is coincident with the load vector. A positive pressure is produced in the converging region of the clearance. Downstream from the minimum film thickness, which occurs along the line of centers, the film becomes divergent. The resistance decreases in the direction of pumping, and either negative pressures occur or the air in the lubricant gasifies or cavitates and a region of atmospheric pressure occurs in the bearing area. This phenomenon is known as *fluid film bearing cavitation*. It should be clearly distinguished from other forms of cavitation that take place in pumps, such as in the impeller, for example. Here the fluid is traveling at a high velocity and the inertia forces on each fluid element dominate. Implosions occur in the impeller and can cause damage.

In a bearing, the viscous forces dominate and each fluid particle moves at a constant velocity in proportion to the net shearing forces on it. Thus, cavitation in a bearing is more of a change of the phase of the lubricant that occurs in a region of lower pressure that permits the release of entrained gases. Generally, bearing cavitation does not cause damage.

Regimes of Lubrication Whether or not a fluid film can be formed, journal rotation is dependent on several factors including the surface speed, viscosity, and load capacity. A parameter¹ is often used to determine a particular regime of lubrication, ZN/\bar{P} , where

Z = viscosity of lubricant, cP (Pa · s)

N = rotating speed, rpm

\bar{P} = average pressure of the bearing, lb/in² (bar)*

A plot of the coefficient of friction versus ZN/\bar{P} generally has the form shown in Figure 2. At low values of ZN/\bar{P} , a combination of viscosity, speed, and load places a bearing in a boundary lubricated regime where typical coefficients of friction are 0.08 to 0.14. Boundary lubrication implies intimate contact between the opposed surfaces. As the value of the parameter increases as a result of the increased speed, increased viscosity, or lowered load, there is a dramatic reduction in the coefficient of friction. In this region, there is a mixed film lubrication and the coefficient of friction varies between 0.02 and 0.08. By mixed film lubrication, it is meant that the journal is partly surrounded by a fluid film and is partly supported by rubbing contact between the opposed members. As ZN/\bar{P} increases

FIGURE 2 Coefficient of friction versus ZN/\bar{P} (Ref. 1).

*1 bar = 10⁵ Pa. For a discussion of bar, see "SI Units: A Commentary" in the front matter.

further, a situation of full fluid film lubrication prevails.

A general rule of thumb is that ZN/\bar{P} should be 30 (0.44) or greater for a fluid film to be generated. Note that as ZN/\bar{P} continues to increase beyond the full film demarcation, the coefficient of friction rises, but at a relatively low rate and generally remains in regions of low coefficients of friction.

EXAMPLE

$$\begin{aligned} Z &= 30 \text{ cP (0.03 Pa} \cdot \text{s)} \\ N &= 150 \text{ rpm} \\ \bar{P} &= 200 \text{ lb/in}^2 \text{ (13.6 bar)} \\ \frac{ZN}{\bar{P}} &= \frac{30 \times 150}{200} = 22.5 \end{aligned}$$

The bearing is not fluidborne and is operating in the mixed film regime. At what speed will the bearing become hydrodynamic? For hydrodynamic operations, $ZN/\bar{P} = 30$. Therefore,

$$N = \frac{30\bar{P}}{Z} = \frac{30 \times 200}{30} = 200 \text{ rpm}$$

THEORETICAL FOUNDATIONS

The foundation of a fluid film-bearing analysis emanates from the boundary layer theory of fluid mechanics. The governing differential equation was first formulated by Osborne Reynolds in 1886 and is known as Reynolds' equation in his honor. It has been only in the last 30 years or so that general solutions have been obtained, and this has been primarily due to the use of numerical methods applied to the digital computer. References 2 and 3 go into the details of contemporary numerical solutions and are recommended for those interested in the analytical aspects of lubrication.

Principal Assumptions Reynolds' equation can be derived from the Navier-Stokes equation of fluid mechanics, and a number of textbooks are available that comprehensively describe the derivation.⁴ The primary assumptions are as follows:

- Laminar flow conditions prevail, and the fluids obey a Newtonian shear stress distribution where the shear stress is proportional to the velocity gradient.
- Inertial forces, resulting from acceleration of the liquid, are small relative to the viscous shear forces and may be neglected.
- The pressure across the film is constant since the fluid films are so thin.
- The height of the fluid film is small relative to other geometric dimensions, and so the curvature of the fluid film can be ignored.
- The viscosity of the liquid remains constant. In most cases, this is a reasonable assumption since it has been repeatedly demonstrated that, if the average viscosity is used, little error is introduced and the complexity of the analysis is considerably reduced.

Derivation of Reynold's Equation of Lubrication Assume that the rotating journal has a peripheral velocity U . Consider an elemental volume in the clearance space of the bearing and establish equilibrium (see Figure 3). Note that since inertial forces are neglected, the volume is in equilibrium by the pressure and shear forces acting upon it, so there is no acceleration. As shown in Figure 4, p is the pressure and τ is the shear stress acting upon the volume. Summing forces in the x direction

FIGURE 3 Fluid control volume.

FIGURE 4 Force equilibrium on fluid element.

FIGURE 5 Laminar velocity distribution across film.

$$p \, dy \, dz - \left(p + \frac{\partial p}{\partial x} dx \right) dy \, dz - \tau \, dx \, dz + \left(\tau + \frac{\partial \tau}{\partial y} dy \right) dx \, dz = 0 \quad (1)$$

$$- \frac{\partial p}{\partial x} dx \, dy \, dz + \frac{\partial \tau}{\partial y} dx \, dy \, dz = 0$$

or

$$\frac{\partial p}{\partial x} = \frac{\partial \tau}{\partial y} \quad (2)$$

For a Newtonian fluid in a laminar flow, the shear stress is directly related to the velocity gradient with the proportionality constant being the absolute viscosity μ (see Figure 5):

$$\tau = \mu \frac{dv}{dy} \quad (3)$$

$$\frac{\partial \tau}{\partial y} = \mu \frac{\partial^2 v}{\partial y^2}$$

where v is the fluid velocity. Substituting Equation 3 into Equation 2, we obtain

$$\frac{\partial p}{\partial x} = \mu \frac{\partial^2 v}{\partial y^2} \quad (4)$$

Integrating with respect to y twice produces the following equation:

$$v = \frac{1}{\mu} \frac{\partial p}{\partial x} \frac{y^2}{2} + C_1 y + C_2 \quad (5)$$

where C_1 and C_2 are constants of integration. The boundary conditions are

$$v = 0, y = 0 \text{ and} \quad (6)$$

$$v = u, y = h$$

Substituting the boundary conditions of Equation 6 into Equation 5 results in the following expression for v :

$$v = \frac{1}{2\mu} \frac{\partial p}{\partial x} (y^2 - h^2 y) + \frac{uy}{2} \quad (7)$$

The velocity in the z direction would be similar, except that the surface velocity term would be omitted because no surface velocity exists in the z direction. In addition, the pressure gradient would be with respect to z .

Now let us consider the flow across the film due to this velocity. Note that Equation 7 is the velocity computed in the x direction, which is in the direction of rotation of the journal:

$$q_x = \int_0^h v_x dy = \int_0^h \left[\frac{1}{2\mu} \frac{\partial p}{\partial x} (y^2 - h^2 y) + \frac{uy}{2} \right] dy \quad (8)$$

After integrating,

$$q_x = -\frac{1}{12\mu} \frac{\partial p}{\partial x} h^3 + \frac{1}{2} uh \quad (9)$$

Note that q_x is the flow per unit width across the film. The flow in the axial direction is

$$q_z = -\frac{1}{12\mu} \frac{\partial p}{\partial z} h^3 \quad (10)$$

Now let us consider a flow balance through an elemental volume across the film (see Figure 6). The net outflow through the volume equals the net reduction in volume per unit time:

$$\left(q_x + \frac{\partial q_x}{\partial x} dx \right) dz - q_x dz + \left(q_z + \frac{\partial q_z}{\partial z} dz \right) dx - q_z dx = -\frac{\partial h}{\partial t} dx dz \quad (11)$$

Thus, this gives us

$$\frac{\partial q_x}{\partial x} + \frac{\partial q_z}{\partial z} = -\frac{\partial h}{\partial t} \quad (12)$$

Substituting Equations 9 and 10 into Equation 12, we obtain

$$-\frac{\partial}{\partial x} \left(\frac{1}{12\mu} h^3 \frac{\partial p}{\partial x} \right) - \frac{\partial}{\partial z} \left(\frac{1}{12\mu} h^3 \frac{\partial p}{\partial z} \right) = -\frac{\partial h}{\partial t} - \frac{u}{2} \frac{\partial h}{\partial x} \quad (13)$$

and the final equation becomes

$$\frac{\partial}{\partial x} \left(\frac{h^3}{\mu} \frac{\partial p}{\partial x} \right) + \frac{\partial}{\partial z} \left(\frac{h^3}{\mu} \frac{\partial p}{\partial z} \right) = 6\mu \frac{\partial h}{\partial x} + 12 \frac{\partial h}{\partial t} \quad (14)$$

Equation 14 is the general form of Reynolds' equation used for laminar, two-dimensional lubrication problems.

Reynolds' equation is a flow balance equation. The left-hand side represents pressure-induced flows in the x and z directions through the differential element. The first term on the right-hand side represents the shear flow of the fluid induced by the surface velocity of the journal u . Note that this term contains the derivative of clearance with respect to distance. If this term is zero, then there is zero pressure produced by hydrodynamic action,

FIGURE 6 Flow balance across control volume.

and the term $\partial h/\partial x$ is the mathematical representation of the tapered wedge. The second term on the right-hand side refers to a time rate of change of the film thickness, which can be translated to a normal velocity of the center of the journal. It produces pressure by a fluid velocity normal to the bearing surfaces that attempts to squeeze fluid out of a restricted clearance space. This phenomenon is called the squeeze film effect in bearing terminology. Since it is proportional to the velocity of the center of the journal, it is the phenomenon that produces viscous damping in a bearing.

The solution to Reynolds' equation (refer to Equation 14) provides the pressure at all points in the bearing. The application of the digital computer has enabled a rapid solution of Reynolds' equation over a grid network representing the bearing area.^{2,3}

Once the pressures have been obtained, a numerical integration is applied to determine the performance parameters (in other words, the load capacity):

$$w = \iint p r d\theta dr \quad (15)$$

The flow across any circumferential line is

$$q_\theta = \oint \left(-\frac{1}{12\mu} \frac{\partial p}{r \partial \theta} h^3 + \frac{1}{2} u h \right) dz \quad (16)$$

The flow across any axial line is

$$q_z = \oint \left(-\frac{1}{12\mu} \frac{\partial p}{\partial z} h^3 \right) r d\theta \quad (17)$$

The viscous frictional moment is obtained by integrating the shear stress over the area and can be shown to be

$$M_f = \iint \left[\frac{1}{r} \frac{\partial p}{\partial \theta} \frac{h}{2} + \frac{\mu r \omega}{h} \right] r^2 d\theta dz \quad (18)$$

where ω = journal surface speed, rad/s.

Typical computer program output includes the following:

- Pressure distribution throughout the grid network
- Load capacity
- Side leakage and carryover flows
- Viscous power losses
- Righting moments due to misalignments
- Attitude angles
- Cross-coupled spring and damping coefficients due to displacements and velocity perturbations of the journal center
- Clearance distribution

Turbulence Equation 14 is for laminar conditions. For very high speed bearings, operations beyond the turbulent regime may occur and Reynolds' equation must be modified. The turbulent theory has been developed, and the literature on this topic can enable performance predictions for turbulent bearings.^{5,6}

The onset of turbulence is determined by examining the bearing's Reynolds number, which is the ratio of inertia to viscous forces and is defined as

$$Re = \frac{\rho u h}{\mu} \quad (19)$$

where Re = Reynolds number

ρ = fluid density, lb · s²/in⁴ (kg/m³)

u = surface velocity, in/s (m/s)

h = local film thickness, in (m)

μ = viscosity, lb · s/in² (Pa · s)

A reasonable approximation is to use the concentric clearance c for h . In terms of N rpm and journal diameter D , the Reynolds number is

$$Re = \rho \frac{\pi D N}{60} \frac{c}{\mu} \quad (20)$$

The criterion for turbulence in journal bearings is that $Re \geq 1000$.

EXAMPLE As an example, consider the following:

Journal diameter $D = 5$ in (127 mm)

Bearing length $L = 5$ in (127 mm)

Radial clearance $c = 0.0025$ in (0.064 mm)

Operating speed $N = 5000$ rpm

Lubricant viscosity $\mu = 2 \times 10^{-6}$ lb · s/in² (14×10^{-3} Pa · s)

Lubricant density $\rho = 7.95 \times 10^{-5}$ lb · s²/in⁴ (8.66×10^{-11} kg · s²/mm⁴)

$$\begin{aligned} Re &= \rho \frac{\pi D N}{60} \frac{c}{\mu} \\ &= 7.95 \times 10^{-5} \times \frac{\pi \times 5 \times 5000}{60} \times \frac{0.0025}{2 \times 10^{-6}} = 130 \end{aligned}$$

Thus, the bearing is operating in the laminar regime. To become turbulent (assuming constant viscosity), the operating speed would have to increase to approximately 38,500 rpm.

The example cited is for a relatively high-speed, oil-lubricated bearing for pump applications. In general, most pump bearings operate in the laminar regime. Exceptions might occur when water is used as the lubricant because it is much less viscous than oil.

Evaluation of Frictional Losses It is often desirable to obtain a quick estimate of viscous drag losses that the journal bearings produce. If we consider shear forces again, we return to the laminar flow equation:

$$F = \mu A \frac{\mu}{h} \quad (21)$$

where F = viscous shear force, lb (N)

μ = viscosity, lb · s/in² (Pa · s)

A = surface area, in² (m²)

u = journal velocity, in/s (m/s)

h = film thickness, in (m)

To obtain friction, we multiply both sides of Equation 21 by the journal radius R . Then the viscous frictional moment is

$$M = \mu A R \frac{u}{h}$$

The frictional horsepower loss is

$$FHP = \frac{NM}{63,000}$$

where N = rotating speed, rpm

M = moment, lb · in (N · m)

Also

$$A = \text{surface area of bearing} = \pi DL, \text{ in}^2 (\text{m}^2)$$

$$u = \text{surface speed} = \frac{\pi DN}{60} \text{ in/s (m/s)}$$

Substituting, we obtain

$$FHP = \frac{\mu L D^3 N^2}{766,000h} \quad (22)$$

In obtaining approximate losses for estimation purposes, the concentric clearance c is substituted for the local film thickness h .

If we consider the previous example where $D = 5$ in (127 mm), $L = 5$ in (127 mm), $c = 0.0025$ in (0.064 mm), $N = 5000$ rpm, and $\mu = 2 \times 10^{-6}$ lb · s/in² (14×10^{-3} Pa · s), the horsepower loss is

$$FHP = \frac{(2 \times 10^{-6})(5)(5)^3(5000)^2}{(766,000)(0.0025)} = 16.32 \text{ hp}$$

Note that for thrust bearings, the frictional horsepower loss is

$$FHP = \frac{\mu N^2}{h} \frac{OD^4 - ID^4}{6.127 \times 10^6} \quad (23)$$

where OD = outside diameter

ID = inside diameter

A general rule of thumb is that the frictional horsepower in a thrust bearing is approximately twice that in a journal bearing.

BEARING TYPES

Cylindrical Bearing The most common type of journal bearing is the plain cylindrical bushing shown schematically in Figure 1. It can be split and have lubricating feed grooves at the parting line. A ramification is to incorporate axial grooves to enable better cooling and to improve whirl stability (described in more detail below in the discussion of cylindrical bearings with axial grooves). The principle advantages of cylindrical bearings are (1) simple construction and (2) a high-load capacity relative to other bearing configurations.

This type of bearing also has several disadvantages:

- **Whirl Instability:** This is prone to subsynchronous whirling at high speeds and also at low loads. Whirling is an orbiting of the journal (shaft) center in the bearing, a motion that is superimposed upon the normal journal rotation. The orbital frequency is approximately half the rotating speed of the shaft. The expression *half-frequency whirl* is commonly used. The reason for the occurrence of this whirl and more details concerning bearing dynamics are presented in the section on bearing dynamics.
- **Viscous Heat Generation:** Because of the generally large and uninterrupted surface area of this bearing, it generates more viscous power loss than some other types.

- **Contamination:** The cylindrical bearing is more susceptible to contamination problems than other types because contaminants that are dragged in at the leading edge of the bearing cannot easily dislodge because of the absence of grooves or other escape paths.

The advantages of simplicity and load capacity make the plain journal a leading candidate for most applications, but performance should be carefully investigated for whirl instability and potential thermal problems. Cylindrical bearings are generally used for medium-speed (500 in/s [200 mm/sec] surface speed) and medium- to heavy-load applications (250 to 400 lb/in² [17 to 28 bar] on a projected area).

Cylindrical Bearing with Axial Grooves A typical configuration of this type of bearing is a plain cylindrical bearing with four equally spaced longitudinal grooves extending most of the way through the bearing. Usually, a slight land area exists at either end of the groove to force the inlet flow to each groove into the bearing clearance region (see Figure 7), rather than out the groove ends. This configuration is a little less simple than the plain cylindrical bearing, and because the grooves consume some land area, this configuration has less load capacity than the plain bushing. Since oil is fed into each of the axial grooves, this bearing requires more inlet flow but also will run cooler than the plain bushing. The grooves act as convenient outlets for any contaminants in the lubricant, and thus the grooved bearing can tolerate more contamination than the plain cylindrical bearing.

In general, this bearing can be considered as an alternate to a plain bearing if the former can correct a whirl or overheating problem.

Elliptical and Lobe Bearings Elliptical and lobe bearings have noncircular geometries. Figure 8 shows two types of three-lobe bearings with the clearance distribution exaggerated so that the lobe geometry is easily discernible. An elliptical bearing is simply a two-lobe bearing with the major axis along the horizontal axis.

The lobe bearing shown in Figure 8a is a symmetric lobe bearing where the minimum concentric clearance occurs in the center of each lobed region. Thus, at the leading edge region, a converging clearance produces positive pressure, but downstream from the minimum film thickness, a divergent film thickness distribution can be found with resulting negative, or cavitation, pressures.

The canted lobe in Figure 8b, on the other hand, generally develop positive pressure throughout the lobe because the bearing is constructed with a completely converging film thickness in each lobed region. This design has excellent whirl resistance (superior to that of the symmetric lobe bearing) and a reasonably good load capability. A 2:1 ratio between leading and trailing edge concentric clearance is generally a reasonable compromise with respect to performance.

Elliptical and lobe bearings are often used because they provide better resistance to whirls than cylindrical configurations. They do so because they have multiple load-producing pads that assist in preventing large-attitude angles and cross-coupling (see the section on bearing dynamics). Elliptical and lobe bearings are generally used for high-speed, low-load applications where whirls might be a problem.

FIGURE 7 Cylindrical bearing with axial grooving.

FIGURE 8 (a) symmetric lobe bearing and (b) canted lobe bearing.

FIGURE 9 Five-pad tilting pad bearing.

Elliptical, or two-lobe, bearings generally have poor horizontal stiffness because of the large clearances along the major diameter of the ellipse. The split elliptical configuration, however, is easier to manufacture than the other types because it is two cylindrical bearing halves with material removed along the parting line. Lobe bearings are usually clearance- and tolerance-sensitive. The other types of lobe bearings are complicated to manufacture.

Tilting-Pad Bearings Tilting-pad bearings are used extensively, especially in high-speed applications, because of their whirl characteristics. They are the most whirl-free of all bearing configurations.

An important geometric variable for tilting-pad bearings is the preload ratio, defined as shown in Figure 9.

The preload ratio equals

$$\text{Preload ratio} = PR = \frac{c - c'}{c} = 1 - \frac{c'}{c} \quad (24)$$

where c = machined clearance

c' = concentric pivot film thickness

The variable c' is an installed clearance and is dependent upon the radial position of the pivot. Figure 10 displays two pads. Pad 1 has been installed such that the preload ratio

FIGURE 10 Tilting-pad bearing preload.

is less than one. For pad 2, the preload ratio is one. The solid line represents the position of the journal in the concentric position. The dashed portion of the journal represents its position when a load is applied to the bottom pads (not shown). Pad 1 is operating with a good converging wedge, even though the journal is moving away from it. Pad 2, on the other hand, is operating with a completely diverging film, which means that it is totally unloaded. Thus, bearings with installed pad preload ratios of one or greater will operate with unloaded pads, which reduces overall stiffness of the bearing and results in a deterioration of stability because the unloaded pads do not aid in resisting cross-coupling influences. In the unloaded position, they are also subject to flutter instability and to a phenomenon known as *leading edge lockup*, where the leading edge is forced against the shaft and is maintained in that position by the frictional interaction of the shaft and the pad. This is especially prevalent in bearings that operate with low-viscosity lubricants, such as gas or water bearings. Thus, it is important to design bearings with preload, although for manufacturing reasons it is common practice to produce bearings without preload.

Tilting-pad bearings have some other characteristics that are both positive and negative:

- They are not as clearance-sensitive as most other bearings.
- Because the pads can move, they can operate safely at a lower minimum film thickness than other bearings.
- They do not provide as much squeeze film damping as rigid configurations.
- Generally, they are more expensive than other bearings.
- For high-speed applications, their pivot contacts can be subjected to fretting corrosion.

Hybrid Bearings A hybrid bearing, schematically shown in Figure 11, derives a load capacity from two sources: (1) the normal hydrodynamic pressure generation and (2) an external high-pressure supply that introduces oil into recesses machined into the bearing surface via restrictors (orifices or capillaries upstream of the recesses). External pressure significantly enhances load capacity. Also, these bearings have excellent low- or zero-speed load capabilities. They are sometimes used as startup devices to lift off the rotor. When self-sustaining hydrodynamic speeds are attained, the external pressure is shut off. The characteristics of externally pressurized, or hybrid, bearings include the following:

- High load and stiffness capabilities
- An external flow that assists in cooling

FIGURE 11 Cross-coupling influences in hybrid bearings.

- Their clearances and tolerances are generally more liberal than in hydrodynamic bearings
- They require external fluid-supply systems
- They are applied when there is not a sufficient generating speed or when a high-load capacity and stiffness are required
- They are sometimes applied to prevent a whirl, but rotational speeds can unbalance recess pressures, introduce cross coupling, and promote a whirl.

STEADY STATE PERFORMANCE

Computer-generated performances have been obtained for most of the bearing types previously discussed. Information has been plotted in a nondimensional format so that no restrictions exist on operating conditions, lubricant properties, and so on. Use of the charts will be subsequently demonstrated by numerical example.

Viscosity One of the key parameters in determining the performance of a bearing is the lubricant viscosity. Viscosity characteristics of commonly used Society of Automotive Engineers (SAE) grades of oil are shown in Figure 12. The units of viscosity are *microreyns*, where the reyn has the units of $\text{lb} \cdot \text{s}/\text{in}^2$ and comes from the ratio of shear stress to the velocity gradient across the film, as indicated by Equation 21. Other units of viscosity are *centipoises*, *Saybolt seconds universal* (SSU), and *centistokes*. The conversion factors are as follows:

$$\mu(\text{reyns}) = Z \times 1.45 \times 10^{-7} \quad (25)$$

$$\nu(\text{centistokes}) = 0.22 (\text{SSU}) - \frac{180}{\text{SSU}} \quad (26)$$

$$Z(\text{centipoises}) = \nu(\text{centistokes}) \times \text{SG} (\text{sp. gr.}) \quad (27)$$

FIGURE 12 Viscosity characteristics for SAE oil grades.

Performance Curves Performance plots have been generated for the following types of bearings:

- *Two-groove cylindrical bearings*
- *Symmetric three-lobe bearings:* Each lobe is offset such that in the concentric position the minimum film thickness in the center of each lobed region is half the machined clearance c (see definition following). The pads are each 110° in the angular extent.
- *Canted three-lobe bearing:* The lobing is canted such that in the concentric position the leading edge clearance was twice the trailing edge and the trailing edge film thickness (minimum) in the concentric position was $0.5c$ where c equals the machined clearance. The pads are each 110° in the angular extent.
- *Tilting-pad bearing:* The tilting-pad bearing that information is obtained for is a five-pad bearing with a 60° pad and a preload ratio of 30 percent.

Two length/diameter ratios are examined for each type of bearing: $L/D = 0.5$ and 1.0 . The definition of the nondimensional parameters is as follows:

$$W = \text{nondimensional load parameter} = wc^2/6\mu\omega RL^3 \quad (28)$$

$$P = \text{nondimensional viscous power loss parameter} = 1100cp/\mu(\omega RL)^2 \quad (29)$$

$$Q = \text{nondimensional flow parameter} = 2q/0.26\omega RLc \quad (30)$$

$$HM = \text{nondimensional minimum film thickness} = h_M/c \quad (31)$$

where w = bearing load capacity, lb (N) and

c = reference clearance (machined clearance = radius of bearing – radius of shaft), in (mm)

μ = absolute viscosity, reyns (lb · s/in²) (cP)

ω = shaft or journal rotational speed rad/s

R = shaft radius, in (mm)

L = bearing length, in (mm)

p = viscous power loss, hp (kW)

q = flow, gpm (m³/h)

FIGURE 13 Performance characteristics for two-groove cylindrical bearings.

FIGURE 14 Performance characteristics for three-lobe bearings.

q_i = inlet flow to the leading edge of bearing (for multipad bearings, equals the sum of inlet flow to each pad), gpm (m^3/h)

q_s = side leakage flow or flow out of the bearing ends (for multipad bearings, equals the sum of side leakage flow of each pad), gpm (m^3/h)

h_M = minimum film thickness in bearing, in (mm)

Performance curves are shown in Figures 13 through 17.

At times, the nondimensional data can be confusing and lead to erroneous judgments. For example, the nondimensional power loss P is greater for an L/D equal to 0.5 than for an L/D equal to 1.0. However, when the dimensional value of the power loss is being computed, the nondimensional value is multiplied by L^2 . Therefore, the power loss for the L/D

FIGURE 15 Performance characteristics for canted three-lobe bearings.

FIGURE 16 Performance characteristics for tilting-pad bearings.

equal to 1.0 will be, as expected, greater than for the L/D equal to 0.5. If the reader uses the data as presented, the dimensional information will prove consistent.

To make comparisons among the bearings, using the nondimensional data is not strictly proper because there may be slight inconsistencies in preloads, the bearings will not be operating at the same average viscosity, and so on. Subsequently, dimensional data derived from the performance curves will be compared, but comparisons of the nondimensional information will provide an indication of performance parameters among the bearings. Comparisons have been made at equal values of the load parameter W and the results are shown in Table 1.

Comparisons of the different bearing types should be made only at the same L/D ratio because of the anomalies (discussed above) of nondimensional parameters that occur at

FIGURE 17 Performance characteristics for tilting-pad bearings.

TABLE 1 Comparative Results of Bearing Types at $W = 0.2$

| Bearing type | $L/D = 0.5$ | | | | $L/D = 1$ | | | |
|------------------------|-------------|------|------|------|-----------|------|------|------|
| | P | HM | QS | QI | P | HM | QS | QI |
| Two-groove cylindrical | 1.13 | 0.36 | 0.78 | 1.81 | 0.72 | 0.25 | 0.50 | 1.50 |
| Three-lobe | 1.80 | 0.32 | 0.79 | 1.85 | 1.05 | 0.22 | 0.22 | 1.65 |
| Canted three-lobe | 1.52 | 0.31 | 1.42 | 3.30 | 0.91 | 0.22 | 0.90 | 2.58 |
| Tilting-pad | 1.50 | 0.30 | 0.44 | 2.82 | 0.90 | 0.20 | 0.16 | 1.50 |

QI = nondimensional inlet flow = $2qi/0.26 wRLc$

QS = nondimensional side leakage flow = $2q_s/0.26 wRLc$

different L/D ratios. If we assume that all the reference variables that go into the nondimensional parameters are identical, we can establish the following conclusions:

- The two-groove cylindrical hearing has the highest film thickness and thus the highest load capacity.
- The symmetric three-lobe bearing has the highest power loss.
- The canted three-lobe bearing has the greatest flow requirements.

Note that these comparisons were made on the basis of steady-state performances only. The major reason for applying lobe and tilting-pad bearings is to avoid dynamic instabilities.

Heat Balance Performance is based upon the assumption of a uniform viscosity in the fluid film. Since the viscosity is a strong function of temperature and since the temperature rise of the lubricant due to viscous heat generation is not known a priori, an iterative procedure is required to determine the average viscosity in the film. To determine an average viscosity, there must be a simplified heat balance in the film. The assumption is made that all the viscous heat generated in the film is absorbed by the lubricant as it flows through the film and produces a temperature rise.

FIGURE 18 Heat balance in a fluid film.

Figure 18 shows a developed view of the bearing surface and the parameters involved with conducting the heat balance. The lubricant enters a pad or bearing at the leading edge with an inlet flow q_i and an inlet temperature t_i . As the lubricant enters the bearing surface and flows through it, the lubricant is exposed to a viscous shear, which adds heat to the fluid. In Figure 18, the viscous shear is indicated as a power input p . Some of the fluid flows out of the sides of the bearing, represented by $q_s/2$, and some of the fluid, q_c , is carried either over to the grooving of the next pad or back to the inlet groove for a single pad bearing.

Although the fluid temperature, and thus the viscosity, changes along the length of the pad, it is assumed that the temperature in the film increases to some value t_o for both the side leakage and carry-over fluids. Then the heat balance is conducted as follows:

Heat added to a fluid by a viscous shear equals heat absorbed by the fluid.

$$\text{Heat added to fluid by viscous shear} = \text{heat absorbed by fluid} \quad (32)$$

$$pJ = q_s \rho C_p (t_o - t_i) = q_c \rho C_p (t_o - t_i) = (q_s + q_c) \rho C_p (t_o - t_i)$$

Since by continuity of flow,

$$q_i = q_s + q_c \quad (33)$$

$$pJ = q_i \rho C_p \Delta t \quad (34)$$

$$\Delta t = \frac{pJ}{q_i \rho C_p} \quad (35)$$

where p = viscous heat generation, hp

J = heat equivalent constant = 0.7069 Btu/hp · s (J/kg · s)

ρ = specific weight of flow, lb/in³ (kg/m³)

C_p = specific heat of fluid, Btu/lb · °F (J/kg · °C)

q_i = bearing inlet flow, in³/s (mm³/s)

Δt = temperature rise, °F (°C)

If q_i is in gallons per minute [(1 in³/s = 0.26 gpm) = 16.39 cm³/s],

$$\Delta t = \frac{0.7069(0.26)p}{q_i \rho C_p} = \frac{0.1838p}{q_i \rho C_p} \quad (36)$$

Before proceeding to a sample problem, a word about the flows q_i and q_s , and the general heat balance philosophy. The flow required by the bearing to prevent starvation is q_i . The minimum make-up flow, or the flow that is lost from the ends of the bearing, is the side leakage q_s . Theoretically then, the only flow that need be supplied to the bearing is q_s . However, if this were true, then the heat balance formulation would require another balance between the carry-over flow q_c at some temperature t_o and the make-up flow q_s coming into the pad at temperature t_i . It would be found that, if we supplied only q_s to the bearing, excessive temperatures would result. In most instances, the amount of flow supplied to a bearing exceeds both the inlet flow and the side leakage flow by a significant

margin. Designers often determine the flow to be supplied to a bearing system by a bulk temperature rise of the total flow entering the inlet pipe and exiting the exhaust pipe. Thus, the entire bearing is treated as a black box, and the total flow q_T to the bearing system for a given bulk temperature rise Δt_i is

$$q_T = \frac{pJ}{\rho C_p \Delta t_i} \quad (37)$$

Normally, Δt_i is selected between 20 and 40°F. Since q_T will exceed q_i , not all the flow will enter the film. Some will surround the bearing or flow through the feed groove and act as a cooling medium for heat transfer through the bearing walls or for cooling the fluid that does enter the bearing surface q_i .

EXAMPLE This example demonstrates the use of the design curves and how to perform a simplified heat balance in a bearing analysis.

In this example, we know these values:

Bearing type: two-groove cylindrical

Bearing length $L = 3$ in (76 mm)

Bearing diameter $D = 6$ in (152 mm)

$L/D = 0.5$

$N = 1800$ rpm; $\omega = 1800 \times \pi/30 = 188.5$ rad/s

Bearing load $\omega = 6000$ lb (2721 kg)

Inlet temperature $t_i = 120^\circ\text{F}$ (49°C)

Lubricant = SAE 20

Bearing radial clearance $c = 0.003$ in (0.076 mm)

NOTE: A general rule of thumb is that $c/R = 0.001$.

Assume an average lubricant temperature of $130^\circ\text{F} - \mu$ (SAE 20 at 130°F) = 4.5×10^{-6} reyn ($\text{lb} \cdot \text{s}/\text{in}^2$) (31×10^{-3} Pa \cdot s)

$$\rho = 0.0307 \text{ lb}/\text{in}^3 (849.7 \text{ kg}/\text{m}^3) \text{ (average value for most oils)}$$

$$C_p = 0.5 \text{ Btu}/\text{lb} \cdot ^\circ\text{F} (2093 \text{ J}/\text{kg} \cdot ^\circ\text{C}) \text{ (average value for most oils)}$$

Compute the following:

$$W = \frac{wc^2}{6\mu\omega RL^3} = \frac{(6000)(0.003^2)}{(6)(4.5 \times 10^{-6})(188.5)(3)(3^3)} = 0.1309$$

From Figure 13 and Equation 29,

$$P = 1.0 = \frac{1100cp}{\mu(\omega RL)^2}$$

$$P = \frac{(1)(4.5 \times 10^{-6})(188.5 \times 3 \times 3)^2}{(1100)(0.003)} = 3.92 \text{ hp (2.95 kW)}$$

From Figure 13 and Equation 30,

$$Q_i = 1.85 = \frac{2q_i}{0.26\omega RLC}$$

$$q_i = \frac{(1.85)(0.26)(188.5)(3)(3)(0.003)}{2} = 1.224 \text{ gpm (4.63 l/min)}$$

From Equation 36,

$$\Delta t = \frac{0.1838p}{q_i \rho C_p} = \frac{(0.1838)(3.92)}{(1.224)(0.0307)(0.5)} = 38.35 \text{ F}^\circ (21.3 \text{ C}^\circ)$$

$$t_{av} = \frac{t_i + (t_i + \Delta t)}{2} = \frac{2t_i + \Delta t}{2} = \frac{(2)(120) + 38.85}{2} = 139.2^\circ\text{F} (59.6^\circ\text{C})$$

The assumed t_{av} of 130°F was apparently not high enough and therefore we must repeat the calculations with a higher value of assumed t_{av} . Assume $t_{av} = 138^\circ\text{F}$, $\mu = 3.8 \times 10^{-6} \text{ lb} \cdot \text{s/in}^2 (26.2 \times 10^{-3} \text{ Pa} \cdot \text{s})$ and repeat the calculations:

$$W = \frac{5.8945 \times 10^{-7}}{\mu} = 0.1552$$

$$P = 1.08 = (1.1466 \times 10^{-6}) \left(\frac{P}{\mu} \right)$$

$$p = \frac{(1.08)(3.8 \times 10^{-6})}{1.1466 \times 10^{-6}} = 3.579 \text{ hp} (2.67 \text{ kW})$$

$$QI = 1.83 = \frac{q_i}{0.6616}$$

$$q_i = 1.211 \text{ gpm} (4.58 \text{ l/min})$$

$$\Delta t = 11.974 \frac{p}{q_i} = \frac{(11.974)(3.579)}{1.211} = 35.38 \text{ F}^\circ (19.65 \text{ C}^\circ)$$

$$t_{av} = \frac{(2)(120) + 35.38}{2} = 137.7^\circ\text{F} (58.7^\circ\text{C})$$

For all practical purposes, these equal the assumed value of $t_{av} = 138^\circ\text{F} (58.9^\circ\text{C})$.

In conducting the iterative procedure for determining the average fluid temperature, it is sometimes helpful to plot points on a viscosity chart. Referring to Figure 19, suppose

2.2.5 CENTRIFUGAL PUMP OIL FILM JOURNAL BEARINGS

FIGURE 19 Graphical determination of average viscosity for SAE 20 oil.

point 1 is the resultant average viscosity and temperature of the initial guess and point 2 represents the result of the second guess. Then, by drawing a straight line between points 1 and 2 and establishing where it intersects the lubricant viscosity curve, we can determine the convergence to the proper result of average viscosity and temperature.

Now that we have convergence, we can determine the remaining variables, which are the minimum film thickness H_M and side leakage Q_s from Figure 13:

$$\begin{aligned} HM &= 0.41 = \frac{h_M}{c} \\ h_M &= (0.41)(0.003) = 0.00123 \text{ in (0.031 mm)} \\ QS &= 0.74 = \frac{2q_s}{0.26\omega RLC} = \frac{q_s}{0.6616} \\ q_s &= (0.6616)(0.74) = 0.490 \text{ gpm (1.85 l/min)} \end{aligned}$$

A summary of the total bearing performance is as follows:

- Load $\omega = 6000 \text{ lb (2721 kg)}$
- Minimum film thickness $h_M = 0.00123 \text{ in (0.031 mm)}$
- Viscous power loss $\rho = 3.579 \text{ (2.669 kW)}$
- Inlet flow $q_i = 1.211 \text{ gpm (4.58 l/min)}$
- Side leakage $q_s = 0.490 \text{ gpm (1.85 l/min)}$
- Fluid temperature rise $\Delta t = 35.38^\circ\text{F (19.65}^\circ\text{C)}$

We can repeat the same calculation for the other types of bearings, using Figures 14 through 17. The results are shown in Table 2.

The two-groove cylindrical bearing operates with the highest film thickness. The symmetric three-lobe has the lowest film thickness and highest temperature rise. It appears that, on the basis of steady-state performance, manufacture, and cost, the two-groove cylindrical bearing is the best choice.

BEARING DYNAMICS⁷

Fluid film bearings can significantly influence the dynamics of rotating shafts. They are a primary source of damping and thus can inhibit vibrations. Alternatively, they provide a

mechanism for self-excited rotor whirl. Whirl is manifest as an orbiting of the journal at a subsynchronous frequency, usually close to one-half the rotating speed. Whirl is usually destructive and must be avoided.

It is the purpose of this section to provide some insight into bearing dynamics, present some background on analytical methods and representations, and discuss some particular bearings and factors that can influence dynamic characteristics. Dynamic performance data and sample problems are presented for several bearing types.

The Concept of Cross Coupling As mentioned in the opening paragraphs of this subsection, a journal bearing derives load capacity from viscous pumping of the lubricant through a small clearance region. To generate pressure, the resistance to pumping must increase in the direction of the fluid flow. This is accomplished by a movement of the journal such that the clearance distribution takes on the form of a tapered wedge in the direction of rotation, as shown in Figure 1.

The attitude angle γ in Figure 1 is the angle between the load direction and the line of centers. Thus, the displacement of the journal is not along a line that is coincident with the load vector, and a load in one direction causes not only displacements in that direction, but orthogonal displacements as well.

Similarly, a displacement of the journal in the bearing will cause a load opposing the displacement and a load orthogonal to it. Thus, strong cross-coupling influences are introduced by the mechanism by which a bearing operates. The concept of cross-coupling is significant in dynamic characteristics.

It is the cross-coupling characteristics of a journal bearing that can promote self-excited instabilities in the form of bearing whirl. Motion in one direction produces orthogonal forces that in turn cause orthogonal motion. The process continues, and an orbital motion of the journal results. This orbital motion is generally in the same direction as shaft rotation and subsynchronous in frequency. Half-frequency whirl is a self-excited phenomenon and does not require external forces to promote it.

Cross-Coupled Spring and Damping Coefficients For dynamic considerations, a convenient representation of bearing characteristics is a cross-coupled spring and damping coefficients. These are obtained as follows (refer to Figure 1):

1. The equilibrium position to support the given load is established by computer solution of Reynolds' equation.
2. A small displacement to the journal is applied in the y direction. A new solution of Reynolds' equation is obtained, and the resulting forces in the x and y directions are produced. The spring coefficients are as follows:

$$K_{xy} = \frac{\Delta F_x}{\Delta y} \quad (38)$$

$$K_{yy} = \frac{\Delta F_y}{\Delta y} \quad (39)$$

where K_{xy} = the stiffness in the x direction due to y displacement
 ΔF_x = the difference in x forces between displaced and equilibrium positions
 Δy = the displacement from the equilibrium position in the y direction
 K_{yy} = the stiffness in the y direction due to y displacement
 ΔF_y = the difference in y forces between displaced and equilibrium positions

3. The journal is returned to its equilibrium position and an x displacement is applied. Similar reasoning produces K_{xx} and K_{yx} .

The cross-coupled damping coefficients are produced in a similar manner, except, instead of displacements in the x and y direction, velocities in these directions are consecutively applied with the journal in the equilibrium position. The mechanism for increasing the load capacity is squeeze film in which the last term on the right-hand side of

Equation 14 is actuated. Thus, for most fixed bearing configurations, eight coefficients exist: four spring and four damping. The total force on the journal is

$$F_i = K_{ij}x_j + D_{ij}\dot{x}_j \quad (40)$$

where F_i = force in the i th direction.

Repeated subscripts imply the following summation:

$$K_{ij}x_j = K_{ix}x + K_{iy}y + \dots$$

It should be realized that the cross-coupled spring and damping coefficients represent a linearization of bearing characteristics. When they are used, the equilibrium position should be accurately determined, as the coefficients are valid for only a small displacement region encompassing the equilibrium position of the journal. This is true because the spring and damping coefficients remain constant for only a small region of the equilibrium position.

Consider the two-groove cylindrical bearing shown in Figure 1, with the geometric and operating conditions indicated in Table 3. The computer solution (also the performance curves in Figure 13) produces the following results:

Bearing load $w = 20,780$ lb (9,424 kg)

Power loss = 15.51 hp (11.56 kW)

Minimum film thickness $h_M = 0.00125$ in (0.032 mm)

Side leakage $q_s = 0.941$ gpm (3.56 l/mm)

The spring and damping coefficients are

Spring coefficients, lb/in (kg/mm):

$$\begin{bmatrix} K_{xx} & K_{xy} \\ K_{yx} & K_{yy} \end{bmatrix} = \begin{bmatrix} -12.14 \times 10^6 & -4.64 \times 10^6 \\ 28.3 \times 10^6 & -20.41 \times 10^6 \end{bmatrix}$$

Damping coefficients, lb · s/in kg · s/in:

$$\begin{bmatrix} D_{xx} & D_{xy} \\ D_{yx} & D_{yy} \end{bmatrix} = \begin{bmatrix} -2.85 \times 10^4 & 2.66 \times 10^4 \\ -2.69 \times 10^4 & -1.11 \times 10^5 \end{bmatrix}$$

The negative signs imply a positive stiffness because the restoring load is opposite the applied load. Note that for this bearing configuration there is very strong cross-coupling, evidenced by the magnitude of the off-diagonal terms.

Critical Mass The cross-coupled spring and damping coefficients provide a convenient way of representing a bearing in a stability analysis. They reduce the fluid film bearing to a spring-mass system (see Figure 20), and consequently stability and dynamics problems are simplified considerably.

Consider a journal of mass M operating in a bearing. The journal can be considered to have two degrees of freedom, x and y . The governing equations are

TABLE 3 Two-Groove Cylindrical Bearing Geometry and Operating Conditions

FIGURE 20 Point mass representation of a bearing supported on cross-coupled springs and dampers.

Interpretation of $\chi = \chi_0 e^{\beta t}$

where

$$\beta = \alpha + i\omega$$

$$\chi = \chi_0 e^{\alpha t} e^{i\omega t} = \chi_0 e^{\alpha t} (\cos \omega t + i \sin \omega t)$$

FIGURE 21 Interpretation of the growth factor α and orbital frequency ω .

$$M\ddot{x} + D_{xx}\dot{x} + D_{xy}\dot{y} + K_{xx}x + K_{xy}y = 0 \quad (41)$$

$$M\ddot{y} + D_{yy}\dot{y} + D_{yx}\dot{x} + K_{yy}y + K_{yx}x = 0 \quad (42)$$

Assume a sinusoidal response to the form

$$x = x_0 e^{\beta t} \quad (43)$$

$$y = y_0 e^{\beta t} \quad (44)$$

where β is a complex variable:

$$\beta = \alpha + i\omega \quad (45)$$

By the Euler expansion of $e^{\beta t}$, another way to write Equations 43 and 44 is

$$x = x_0 e^{\alpha t} (\cos \omega t + i \sin \omega t) \quad (46)$$

$$y = y_0 e^{\alpha t} (\cos \omega t + i \sin \omega t) \quad (47)$$

An interpretation of α and ω is shown in Figure 21. The real part of $\beta = \alpha$ is called the *growth or attenuation factor*. The imaginary part is the frequency of vibration. A positive real part means that the response to a disturbance grows in time. The growth factor is similar to the logarithmic mean decrement, which is common in vibration theory:

$$\alpha \tau = \ln \frac{x_{n+1}}{x_n} \quad (48)$$

where τ = period of vibration
 x_{n+1} = amplitude at time $n + 1$
 x_n = amplitude at time n

Thus, the growth factor α is a measure of the growth or decay of the journal to a small disturbance. A positive growth factor implies an instability.

The solutions to Equations 41 and 42 are obtained by substituting Equations 43 and 44, which produces the following:

$$\begin{bmatrix} (M\beta^2 + D_{xx}\beta + K_{xx}) & (D_{xy}\beta + K_{xy}) \\ (\beta D_{yx} + K_{yx}) & (M\beta^2 + \beta D_{yy} + K_{yy}) \end{bmatrix} \begin{Bmatrix} x_0 \\ y_0 \end{Bmatrix} = \{0\}$$

To obtain a solution, the determinant of the coefficient matrix must vanish. Expansion produces a polynomial in β that can be solved for the roots of β , which in turn provide the growth factors and frequencies of vibration.

It is possible to obtain a closed-form solution of Equations 41 and 42 for the critical mass and resulting orbital frequency. The critical mass M is defined as that mass above which an instability will occur. At the threshold of instability, the real part of $\beta = \alpha$ goes to zero and $\beta = i\omega$.

Substituting into Equation 49, expanding the determinant and separating real and imaginary components produces the following equations:

$$M^2\omega^4 - \underbrace{M(K_{yy} + K_{xx})\omega^2}_A + \underbrace{(D_{yx}D_{xy} - D_{xx}D_{yy})\omega^2}_B + \underbrace{K_{xx}K_{yy} - K_{xy}K_{yx}}_C = 0 \quad (50)$$

$$\underbrace{M(D_{yy} + D_{xx})\omega^2}_D + \underbrace{(D_{xy}K_{yx} + D_{yx}K_{xy} - D_{xx}K_{yy} - D_{yy}K_{xx})}_E = 0 \quad (51)$$

The two equations can be solved for M and ω :

$$M = \frac{BED}{E^2 - AED + CD^2} \quad (52)$$

$$\omega = \sqrt{\frac{-(AED + E^2 + CD^2)}{BD^2}} \quad (53)$$

Thus, if the cross-coupled coefficients are known, it is possible to determine the critical mass and the orbital frequency. If the mass acting on the bearing exceeds or equals the critical value, then an instability will occur.

Dynamic Stability of Various Bearing Types Several parameters can be used to establish the stability characteristics of a particular type of bearing. The most significant is the critical mass, derived above. It is also possible to get some feel for stability from purely steady-state performances by examining the bearing attitude angle. The larger the attitude angle, the greater the cross-coupling influence and the worse the stability characteristics. Interpreting attitude angles, however, can prove misleading.

Figure 22 shows plots of the attitude angle γ versus the load parameter W for some of the different types of bearings previously described. The contradiction in these results is that the symmetric three-lobe bearing has higher attitude angles than the two-groove cylindrical bearing even though, as will be subsequently demonstrated, it has superior stability characteristics. The reason for the higher attitude angle is that the bearing is cavitating in the diverging region of the loaded pad, which results in a large shift in the journal. Whirl motion, however, is prevented by the accompanying lobes.

A more direct and accurate approach to establishing bearing stability is to determine the critical mass acting on the bearing. Figure 23 shows the results obtained for the fixed

CENTRIFUGAL PUMPS

FIGURE 22 Attitude angle versus load parameter for various bearing types.

FIGURE 23 Critical mass versus load parameter for various bearing types.

bearing geometries previously discussed. For any particular bearing geometry, if the critical mass attributable to the bearing exceeds that of the data plotted, the bearing will be unstable. Thus, if the plotted point falls to the right of the bearing line, the bearing is stable; if it falls to the left, the bearing is unstable.

The critical mass is defined as follows:

$$M = m\omega R c^3 / 24\mu L^5 \quad (54)$$

- where M = nondimensional critical mass
 m = dimensional critical mass, $\text{lb} \cdot \text{s}^2/\text{in}$ ($\text{kg} \cdot \text{s}^2/\text{mm}$)
 ω = shaft speed, rad/s
 R = shaft radius, in (mm)
 c = bearing machined radial clearance, in (mm)
 μ = lubricant viscosity, lb sec/in^2 ($\text{Pa} \cdot \text{s}$)
 L = bearing length, in (mm)

An examination of the curves in Figure 23 clearly indicates the superiority of the canted three-lobe bearing and the inferiority of the cylindrical configuration.

EXAMPLE Consider a high-speed bearing for which

- $N = 60,000 \text{ rpm}$
 $\omega = 60,000\pi/30 = 6283 \text{ rad/s}$
 $D = 1 \text{ in (25.4 mm)}$
 $L = 0.5 \text{ in (12.7 mm)}$
 $\mu = 1 \times 10^{-6} \text{ lb} \cdot \text{s/in}^2 (6.9 \times 10^{-3} \text{ Pa} \cdot \text{s})$
 $C = 0.0005 \text{ in (0.013 mm)}$
 $w = 100 \text{ lb (45.35 kg)}$

$$W = \frac{wC^2}{6\mu\omega RL^3} = \frac{(100)(0.0005^2)}{(6)(1 \times 10^{-6})(6283)(0.5)(0.5^3)} = 0.0106$$

The value of M is obtained from Figure 22 and indicated in Table 4 for the various bearing types considered. Dimensional units are also given. Table 4 clearly indicates that the lobe bearings can permit significantly more attributable mass than the cylindrical bearing can. If a symmetric rotor is being supported by two bearings, the cylindrical bearings would be unstable if half the weight of the rotor exceeded 14.7 lb (6.67 kg). The half weights go to 258 lb (117 kg) and 501 lb (227.2 kg) for the symmetric three-lobe and canted three-lobe bearings, respectively. No mention has been made of the tilting-pad bearing because, for all practical purposes, these bearings are always stable.

OPERATING CONDITIONS THAT AFFECT BEARING STABILITY

Cavitation Figure 1 shows a pressure distribution in a journal bearing. Positive pressure is generated in the converging wedge because the journal is pumping fluid through a restriction. On the downstream side of the minimum film thickness, the journal is pumping fluid out of a diverging region. In this region, the pressure decreases. Either the pressure becomes negative, which is defined as pressure below the ambient pressure,

TABLE 4 Stability Comparison Chart

| Bearing type | M | m , $\text{lb} \cdot \text{s}^2/\text{in}$ ($\text{kg} \cdot \text{s}^2/\text{mm}$) | w' , lb (kg) ^a |
|--|------|---|-----------------------------|
| Two-groove cylindrical | 0.02 | 0.038 (6.79×10^{-4}) | 14.7 (6.7) |
| Symmetric three-lobe | 0.85 | 0.668 (11.9×10^{-3}) | 257.9 (117.1) |
| Canted three-lobe | 0.68 | 1.299 ($23.2 > 10^{-3}$) | 501.4 (227.6) |
| $m = \frac{24M\mu h^5}{\omega Rc^3} = \frac{M(24)(10^{-6})(0.5^5)}{(6283)(0.5)(0.0005^3)} = 1.91M$ | | | |

^aThe w' represents the maximum mass in weight units that could act on the bearing.

or the film cavitates and decreases to atmospheric pressure as the lubricant releases entrapped air.

With respect to stability, cavitation is a more desirable condition than the development of negative pressure. From an examination of Figure 1, it can be seen that the negative pressure pulls the journal in an orthogonal direction and increases the cross-coupling. The more eccentric the bearing, the larger the negative pressure or cavitated region.

In lightly loaded bearings that are pressure-fed, negative pressures can occur because pressures in the divergent region have not approached atmospheric pressure. Cavitation does not occur, and the bearing is prone to instability. Thus, the feed pressure and load on a bearing are two additional parameters that affect stability.

Lobe bearings are often used because of their excellent antiwhirl characteristics. Figure 9 earlier showed two types of lobe bearings: symmetric and canted. The symmetric lobe bearing is designed so that, in the concentric position, the minimum film thickness occurs at the center of each lobe. Note that this permits a region of converging film followed by a region of diverging film. Thus, depending upon the ambient pressure, it is possible to have negative pressures in a symmetric lobe bearing. Under very high ambient conditions, a symmetric lobe bearing can go unstable.

The canted lobe bearing is designed to have a completely converging wedge and positive pressure throughout its arc length. Its stability characteristics are superior to those of the symmetric lobe bearing. Its steady-state characteristics are also superior.

Hybrid Bearings At times, externally pressurized bearings are resorted to for stability improvements. The philosophy is that externally pressurized bearings are not subject to high attitude angles, as is the case with hydrodynamic journal bearings. Although this is generally true, hybrid bearings can still be subject to considerable cross-coupling. Figure 11 showed a schematic arrangement of a hybrid bearing. Oil is fed through restrictors from an external source into pocket recesses. From there, it exits into the clearance region between recesses. Lubricant is also pumped into and out of recesses by the rotating shaft by a viscous drag in the same manner as with a purely hydrodynamic bearing.

Consider recess 2 in Figure 11. Oil is pumped from the shaft via a converging wedge, and it augments the pressure in the recess provided by the external system. The net result is a higher pressure in the bearing domain covered by recess 2 than would occur without rotation. Now consider recess 3. Here the journal is pumping fluid out of the recess into a diverging film, so that the hydrodynamic action tends to reduce the pressure in this recess domain. By similar reasoning, it can be shown that recess 4 operates at a lower pressure than recess 1. The net result of these variations in pressure due to rotation is that cross-coupling forces are introduced and the hybrid bearing may not prevent instability.

BEARING MATERIALS AND FAILURE MODES

Materials The most common material used for oil-lubricated fluid film bearings is babbitt. Tin- and lead-based babbitts are relatively soft materials and offer the best insurance against shaft damage. They also enable embedded dirt and contaminants without significant damage.

Two types of babbitts are in common use. One has a tin base (86 to 88 percent), with about three to eight percent copper and four to 14 percent antimony. The other has a lead base with a maximum of 20 percent tin and about 10 to 15 percent antimony. The remainder is principally lead. The physical properties of babbitt are shown in Table 5. The primary limitations of babbitt are operating temperature (300°F [140°C] max) and fatigue strength. The chemical composition of various babbitt alloys are indicated in Table 6.

Tin-based babbitts have better characteristics than lead-based babbitts; they have better corrosion resistance, are less likely to wipe under poor conditions of lubrication, and can be bonded more easily than lead-based materials. Because of cost considerations, however, lead-based babbitts are widely used. The more widely used is the SAE 15 alloy containing one percent arsenic (refer to Table 6).

TABLE 5 Properties of Bearing Alloys

| Bearing material | Brinell hardness at room temperature | Brinell hardness at 30°F (17°F) | Minimum Brinell hardness of shaft | Load carrying capacity, lb/in ² (kg/m ²) | Max operating temperature, °F (°C) |
|--------------------|--------------------------------------|---------------------------------|-----------------------------------|---|------------------------------------|
| Tin-based babbitt | 20–30 | 6–12 | 150 or less | 800–1500 ($5.62 \times 10^5 - 10.55 \times 10^5$) | 300 (149) |
| Lead-based babbitt | 15–20 | 6–12 | 150 or less | 800–1200 ($5.62 \times 10^5 - 8.44 \times 10^5$) | 300 (149) |

| Aluminum | 0.005 | 0.005 | 0.005 | 0.005 | 0.005 |
| Cadmium | — | — | 0.05 | 0.05 | 0.05 |
| Others | 0.2 | 0.2 | 0.2 | 0.2 | 0.2 |

^aThe percentage of minor constituents represents limiting values except as noted.SOURCE: *SAE Handbook*, Society of Automotive Engineers. New York, 1960, p. 201.

Tin-based babbitts do not experience as many corrosion problems as lead-based babbitts. SAE 11 babbitts (containing eight percent antimony and eight percent copper) are used extensively for industrial applications.

Babbitts are bonded to a backing shell of another material, such as steel or bronze, because they are not a good structural material. The thinner the babbitt layer, the greater the fatigue resistance. In automotive applications where resistance to fatigue is important, babbitt thickness is from 0.001 to 0.005 in. (0.02 to 0.12 mm). For pump applications, the thickness varies from $\frac{1}{32}$ to $\frac{1}{8}$ in. (0.8 to 3 mm). The thicker layers provide good conformity and embedability.

Failure Modes The failure modes most commonly found are fatigue, wiping, overheating, corrosion, and wear.

Fatigue occurs because of cyclic loads normal to the bearing surface. Figure 24 shows babbitt fatigue in a 7-in (178-mm) diameter journal bearing from a steam turbine.

Wiping results from surface-to-surface contact and smears the babbitt, as shown in Figure 25. The usual causes of wiping are a bearing overload, insufficient rotational speed to form a film, and loss of lubricant.

FIGURE 24 Babbitt fatigue in a 7-in (178-mm) diameter turbine bearing. (Westinghouse Electric Corp. *Photo originally reproduced in Ref. 8, p.18–19.*)

FIGURE 25 Bearing wipe on a 3-in (76-mm) diameter bearing due to temporary loss of lubricant. (Westinghouse Electric Corp. *Photo originally reproduced in Ref. 8, p.18–25*)

FIGURE 26 Corrosion on a 5-in (127-mm) diameter, lead-based babbitt bearing. (Westinghouse Electric Corp. *Photo originally reproduced in Ref. 8, p. 18–21*)

Overheating is manifest by discoloration of the surface and cracking of the babbitt material. Corrosion is failure by a chemical action. It is more common with lead-based babbitts, which react with acids in the lubricant. Figure 26 shows corrosion damage for a 5-in (127-mm) diameter, lead-based babbitt bearing.

Wear results from contaminants in the film and is evidenced by scoring marks that may be localized or persist around a large circumferential region of the bearing.

CENTRIFUGAL PUMP MAGNETIC BEARINGS

GRAHAM JONES
LARRY HAWKINS
PAUL COOPER

Magnetic bearings maintain the rotor of a pump in suspension through the forces of attraction of a magnetic circuit. Thus, although they bear up the weight and hydraulic loads of the impellers and the shaft, they are not really bearings in the traditional sense of the rotating and stationary surfaces bearing on one another. The supporting magnet circuit for each bearing includes stationary magnets in a stator surrounding the shaft, a laminated rotor that fits on the shaft, and the shaft itself. The stator consists of electromagnets in the traditional heteropolar design, and if a homopolar design is employed, permanent magnets can be added. Sensors monitor the position of the shaft and signal a controller to adjust the magnetic loads to keep the shaft to within about 0.001 in (25 μm) of the desired position.

Magnetic bearings are found in small, high-speed turbomachinery such as high-speed, multistage, axial-flow turbomolecular vacuum pumps¹. They were introduced into large turbomachinery in the early 1980s, mainly in gas compressors and turboexpanders. Their use and acceptance has grown slowly but steadily since then². Pump applications of a significant size have appeared and have confirmed the general position that magnetic bearings can provide a technically sound bearing with maintenance and operating advantages, including zero wear. However, due to the technical complexity of magnetic bearing systems, the economies of scale associated with production quantities are required to make these systems affordable.

Two representative magnetic-bearing-equipped pumps are summarized in Table 1. One is a multistage boiler feedwater pump³⁻⁶ and the other a single-stage double-suction hydrocarbon process pump⁷. The multistage pump was retrofitted with magnetic bearings (as shown in Figure 1) and is shown in Figure 2, together with another identical pump that still contains the oil-lubricated bearings—both installed in an electric generating station. The magnetic-bearing pump is not encumbered with the usual complexity of a bearing lubrication system.

TABLE 1 Example of magnetic-bearing-equipped pumps

| Parameter | Multistage Pump | Single-Stage Pump |
|-------------------------------------|-----------------|---|
| Power, hp (MW) | 610 (0.46) | 800 (0.6) |

MAGNETIC BEARING PRINCIPLES

How Magnetic Bearings Work In an active magnetic bearing system, a stator composed of an array of stationary magnets, or electromagnetic coils, interacts with a ferrous rotor (or a ferrous sleeve on a non-ferrous rotor) so as to suspend the shaft in a magnetic field (see Figure 3).

The position of the shaft is maintained dynamically through a continuous feedback system which comprises a position sensor, a controller, and an amplifier system (see Figure 4). Typically there are two radial bearings and one thrust bearing for a complete sys-

FIGURE 3 Typical radial electromagnetic bearing. (Axial thrust bearings have the stator coils arranged in a disk configuration, a ferrous rotating disk being supported in the resulting magnetic circuit.)

FIGURE 4 Typical system control loop

tem. This system is tuned to the required characteristics of the pump, through a digital or analog controller (Figure 5), with the capability of adjusting the bearing stiffness and damping as a function of pump speed. Alarms and trips can be set at any required rotor offset or bearing load to provide the operator with warnings or to trip the drive unit as necessary. Figure 6 illustrates a typical bearing transfer function, showing a statically stiff bearing, with a dynamic stiffness over the operating speed range designed to meet the rotor dynamics requirements of the unit. The stiffness is then rolled off above the operating range to avoid excitation of higher modes in the rotor or stator.

Controller redundancy can be provided with the control loops switching to backup units upon sensing a failure. Also, backup power supplies should be provided, either through alternate sources or a battery system. Typically the power required is only one or two kW or less.

A catcher (also known as auxiliary, backup, or touchdown) bearing (indicated in Figure 1) is required to protect the rotor stator interface during maintenance and in the event of

FIGURE 5 Controllers for magnetic bearings, containing rectifier and amplifiers: a) digital controller; b) analog controller

FIGURE 6 Bearing transfer function

loss of power or a severe transient beyond the force capability of the bearing. Typically, the catcher bearing is designed for 5 to 20 lifetime drops from full speed, and will be a readily replaceable rolling element or sleeve bearing. The pump of Figures 1 and 2 has rolling element catcher bearings. The radial clearances G_1 (see Figure 7) between the magnetic

FIGURE 7 Clearance arrangement: Seal ring clearance G3 is greater than catcher-bearing clearance G2, but is less than magnetic-bearing clearance G1.

bearing stator and rotor are of the order of 20 to 40 mil (0.5 to 1 mm), and those in the catcher bearings (G2) are about half of that value.

Reasons for Using Magnetic Bearings There are several reasons to use magnetic bearings in pumps. While any one of these reasons may not be sufficient justification on its own, together they can provide a strong justification.

Reliability is a key incentive. The components of a magnetic bearing are essentially the same components as are found in an electric motor: laminations and coils. Because no wear is involved due to the lack of contact, these components will generally last the life of the equipment involved. Thus maintenance of a magnetic bearing system is transferred from mechanical components inside the pump to the external controller, which has plug-in card replacement maintenance. Pump reliability is therefore improved, whereas repair times and costs are reduced.

Reduced power consumption is a second advantage, with the elimination of all losses associated with fluid film bearings and oil pumping equipment. This is replaced by the smaller power requirements of the bearing controller. Further, if the lifting force is supplied by a permanent magnet, supplemented by an active control circuit, this power requirement can be even smaller.

The ability to submerge the bearing in the pump fluid is a major advantage that allows the outboard mechanical seal to be eliminated, thereby eliminating maintenance and replacement of this seal⁸. [This was not done for the pumps of Table 1 (and Figures 1 and 2), because in both cases magnetic bearings were retrofitted to existing machines.]

More indirect savings are also possible in two other areas. Rotor dynamics can be controlled through the ability to adjust stiffness and damping as a function of pump speed, allowing higher imbalance without the need for shutdown. The diagnostic output inherent in the information provided in the controller can be fed into the overall plant operating system and the short-term and long-term health of the pump and the system can be monitored. This is done by inferring seal wear, transient hydraulic loads, and so on.

The actual figures for the savings possible due to the previous advantages are very pump- and system-specific, and general numbers are not very useful. Reference 9 has developed methodology for considering the economic effect of the types of advantages given.

Main Types of Magnetic Bearings and Their Selection There are two main types of magnetic bearings: passive and active. Passive bearings rely only on permanent magnets in repulsion and provide low stiffness, low damping, and no ability to control either of these parameters. Passive bearings are not applicable to pumps for this reason.

FIGURE 8 Heteropolar and homopolar bearings

Active bearings using the feedback system previously described are essential for pump applications. Within the active bearing systems are the options of heteropolar and homopolar and of electromagnetic and permanent magnet bias. The principles of the heteropolar and homopolar approaches are shown in the Figure 8.

The main difference between the two types is that in the heteropolar design, the bias and control flux flow in the same magnetic circuit radially through the rotor, whereas in the homopolar design the bias flux flows axially along the rotor and only the control flux flows radially through the rotor.

The homopolar design has two options for providing the bias flux for the bearing system¹⁰. One is to use an electromagnetic effect, and the other is to use a permanent magnet. The permanent magnet generation in the homopolar configuration results in a more linear relationship between force and distance. In a simple magnetic circuit, the attraction force of a magnet on a ferromagnetic target decreases as the square of distance (the target cuts $\frac{1}{4}$ as many flux lines at twice the distance). With the permanent magnet in a homopolar circuit, the effect of the air gap is therefore reduced.

DESIGN CONSIDERATIONS

Design Loads The specification of a magnetic bearing requires a different approach to that required for a conventional bearing system. This section identifies the key areas where these differences occur.

The rotor can move considerably within the magnetic bearing and catcher bearing clearances, typically up to 10 mil (0.25 mm), before any contact is involved. Thus the clearances G3 in the internal ring-seal system (see Figure 7) become the key controlling parameter in setting the bearing clearance design limits and in the degree of motion permitted during transients. Thus, very early in the design process, the magnetic bearing clearances, catcher bearing clearances, and sealing-ring clearances must be optimized with due consideration for manufacturing tolerances and assembly concerns.

Synchronous filters or open-loop control methods can be used to handle imbalance loads so that the degree of imbalance acceptable (based on allowable bearing loads and shaft motion within the catcher bearing clearances) can often be significantly greater than in conventional bearings.

There is an area where careful analysis is needed for each new pump configuration. A conventional bearing, if overloaded, will accept the load with a higher wear rate, but a magnetic bearing has a sharp cut-off at the point where the flux saturation level is reached. At that point, any additional load will be transferred to the catcher bearing. Thus it is important to include all loads in the design specification, with the appropriate margins. All applications to date have generally shown a) that there are loads which were mistakenly considered to be insignificant, or b) that the values of the loads were underestimated due to lack of knowledge.

Magnetic bearings also must be carefully designed to handle transient loads, some of which may occur only once in a lifetime. Two approaches can be taken. One is to over-design the bearing to handle the load without contacting the catcher bearing; the other is to allow momentary contact with the catcher bearing. Examples of these types of loads are hydraulic loads, seal touchdown loads, system loads such as water hammer, valve operation, pump switchover, pump to driver alignment loads, and seismic loading.

Rotordynamics Considerations Magnetic bearings have the capability to control the rotor dynamics of a pump very effectively. If the pump is running below its first flexible mode, this is usually straightforward. If the pump has to traverse a flexible mode, the position of the bearings and the position sensor must be such that the modes can be recognized by the position sensor, and the bearings can exert a positive restoring force to control the mode. That is, the position sensors and bearings must not be positioned at or close to a node and certainly not positioned on opposite sides of a mode. Thus, rotordynamics considerations should be taken care of very early in the configuration of the system.

The two typical rigid body modes are shown in Figure 9. The location of the bearing and position sensor is not usually an issue for these modes, but the flexible modes require that the position sensor and bearing be positioned in such a way that the rotor deflection can be measured and the bearing can exert the necessary restoring force and damping to control the mode.

Magnetic bearing controllers are programmed with a transfer function designed specifically for the pump. This transfer function, or control algorithm, provides the necessary stiffness and damping at all operating speeds to control the rotor as previously described.

The key requirements of the transfer function are that it

- Provides correct damping and stiffness to handle the rotor rigid body modes
- Provides sufficient force with the appropriate control bandwidth to handle the rotor flexible modes below the maximum operating speed

FIGURE 9 Flexible mode design considerations

- Does not excite any rotor modes above the maximum operating speed
- Does not excite any stator vibration modes at any frequency
- Takes into account the stiffness and damping contribution from wear rings and inter-stage annular seals

Auxiliary or Catcher Bearings However reliable magnetic bearings become, a landing surface for maintenance will be required. Further, designing a bearing that will take all transient loads without any possibility of overload will usually result in over-sized and costly bearings. Hence catcher, bearings are expected to be required. The design limits for catcher bearings are usually established by calculating the forces that will result from a drop at operating speed.

For applications running at significant speeds, a non-linear analysis is required to determine the motion and loading on the bearing during such a drop. The key design considerations are impact loads, heat generation during the rundown, and the response to imbalance if, when running on the catcher bearings, any critical speeds have to be traversed.

Rolling element bearings have typically been used as catcher bearings; however, sleeve bearings and bushings have been used in several applications, and are better suited to a submerged application.

MAGNETIC BEARING SIZING

The fundamental magnetic bearing sizing problem is to define the pole area at the bearing air gap that is necessary to achieve the desired force capacity without saturating the selected pole materials. Given the pole area, the minimum stator outside diameter and maximum rotor inside diameter can be determined using simple algorithms to ensure that no other part of the magnetic circuit saturates. The stator geometry must also include sufficient volume for the control and bias coils.

Approximate size and load capability Table 2 contains rough approximations for the dimensions of magnetic bearings. (Refer to Figure 1.) These are based on the experience with the pumps of Table 1. Also included are the unit load capabilities, which are given a) for radial bearings in terms of radial load F_r divided by the projected area DL of the active pole area of the bearing at the air gap, and b) for axial thrust bearings in terms of the axial load F_z divided by the active pole area of the runner disk between the inner diameter D_i and the outer diameter D_o . These approximations provide the designer and user with an idea of the design configuration of a magnetic-bearing-equipped pump. The

TABLE 2 Approximate magnetic bearing sizing relationships

| Sizing Parameter | Heteropolar | Homopolar |
|--|-------------|-----------|
| <i>Radial Bearings</i> | | |
| a) Dimensions, in multiples of the shaft diameter | | |
| Air gap diameter, D | 2 | 1.5 |
| Stator outer diameter | 4 | 3 |
| Overall axial length | 2 | 1.5 |
| Active axial length of poles at air gap, L | 0.9 | 0.8 |
| b) Unit load capability, F_r/DL , lb/in ² (MPa) | 40 (0.28)* | 60 (0.41) |
| <i>Axial Thrust Bearings</i> | | |
| a) Diameter ratio D_j/D_o of active pole area | 0.5 | 0.5 |
| b) Unit load capability, $F_z / [\pi(D_o^2 - D_i^2)]$, lb/in ² (MPa) | 50 (0.34)* | 70 (0.48) |

*Higher with special lamination material

low unit loads of magnetic bearings result in more space being needed for them in comparison to conventional bearings.

Theory of One-Dimensional Sizing To perform more accurate, in-depth sizing, the theory of both heteropolar and homopolar magnetic bearings is applied. Magnetic bearing sizing and geometry programs normally use simple one-dimensional magnetic circuit theory to obtain initial sizing and perform design iterations. This initial sizing is then followed up with design analysis using 2D or 3D magnetic FEA analysis to verify the design. The basis of the classic one-dimensional sizing for a magnetic bearing is discussed next, first for the heteropolar bearing and then for the homopolar bearing.

HETEROPOLAR BEARING

- a. *Magnetic circuit*—The basic magnetic circuit equation, derived from Ampere's Loop Law, is

$$MMF = \Phi \mathcal{R} \quad (1)$$

where MMF = magnemotive force

Φ = magnetic flux

\mathcal{R} = path reluctance

A sketch of one quadrant (one electromagnet) of a heteropolar bearing is shown in Figure 10.

Assuming the air gap area and path areas are equal, Eq. 1 becomes

$$2Ni = BA \left(\frac{g}{\mu_o A} + \frac{g}{\mu_o A} + \frac{l_{stat}}{\mu_o \mu_r, stat A} + \frac{l_{rot}}{\mu_o \mu_r, rot A} \right) \quad (2)$$

FIGURE 10 Simple electromagnetic circuit for one quadrant of a heteropolar magnetic bearing

Where N = number of turns per pole

i = coil current

B = magnetic flux density

A = pole area

g = air gap

μ_o = permeability of free space

μ_r = relative permeability

l = iron path length

If the iron permeability is high relative to the air gap ($\mu_{r,rot}, \mu_{r,stat} \gg \mu_o$), the iron reluctance terms are insignificant and the following equation can be obtained for the flux:

$$B = \frac{Ni\mu_o}{g} \quad (3)$$

b. *Force calculation*—The basic force equation for an air gap is

$$F_{gap} = \frac{B^2 A}{2\mu_o} \quad (4)$$

This equation assumes negligible leakage and fringing and that the flux density is uniform in the air gap. The combined vector force along the center of the bearing for the two air gaps of the top magnet is

$$F_{top} = 2F_{gap} \cos \alpha \quad (5)$$

Substituting from Eq. 4 gives

$$F_{top} = \cos \alpha \frac{B^2 A}{\mu_o} \quad (6)$$

If the saturation flux density, B_{sat} , of the iron material is used for B , Eq. 6 defines the load capacity as a function of pole area for a heteropolar magnetic bearing.

c. *Linearization of the force/current characteristic*—Substituting from Eq. 3 gives:

$$F_{top} = \cos \alpha \frac{A}{\mu_o} \left(\frac{Ni\mu_o}{g} \right)^2 = \cos \alpha AN^2 \mu_o \frac{i^2}{g^2} = k_1 \frac{i^2}{g^2} \quad (7)$$

$$k_1 = \cos \alpha AN^2 \mu_o$$

Thus, the force in a given magnet is proportional to the square of the current, a result that makes the bearing more difficult to control. Additionally, a single electromagnet can only apply a force in one direction (an attractive force). For these two reasons, opposed electromagnets are used together with a bias current (or flux) in each coil.

The current relationship is

$$i = i_{bias} + i_{con}$$

to increase the force,

$$i = i_{bias} - i_{con}$$

to decrease the force.

The rotor may also be off-center in the air gap, described by

FIGURE 11 Force versus current for radial bearing of multistage pump

$$g = g_0 - y \quad \text{top air gap}$$

$$g = g_0 + y \quad \text{bottom air gap}$$

Applying Eq. 7 to both top and bottom electromagnets yields

$$F_y = F_{top} - F_{bot} = k_1 \left[\left(\frac{i_{bias} + i_{con}}{g_0 - y} \right)_{top}^2 - \left(\frac{i_{bias} - i_{con}}{g_0 + y} \right)_{bot}^2 \right] \quad (8)$$

With the rotor centered ($y = 0$), this can be reduced to

$$F_y = 4 \frac{k_1}{g_0^2} i_{bias} i_{con} \quad (9)$$

Thus the net bearing force is proportional to the control current. Figures 11 and 12 are examples of measured force versus current for radial and axial thrust bearings respectively. These measurements were made on the magnetic bearing of the multistage pump in Table 1 (refer to Figures 1 and 2).

- d. *Force constant and negative stiffness*—Eq. 8 can be also be linearized for small motion about the center ($y \ll g_0$) by differentiating with respect to i_{con} and y , the two quantities in Eq. 8 that can change in normal operation of the bearing. The result is

$$F_y = -k_f i_{con} - k_n y \quad (10)$$

FIGURE 12 Force versus current for axial thrust bearing of multistage pump

where

$$k_f = \frac{-4k_1 i_{bias}}{g_0^2} = \text{force constant or current stiffness} \quad (11)$$

$$k_n = \frac{-4k_1 i_{bias}^2}{g_0^3} = \text{negative stiffness or position stiffness} \quad (12)$$

The position stiffness is the passive stiffness of the bearing with a bias field but with no control current. The position stiffness is always negative, indicating that if the rotor is displaced from center, it will be pulled further from its equilibrium position if no control current is applied. The force constant defines the relationship of the control force to current (lb/amp or N/amp) with the bearing centered. It is also negative, indicating that applying a control current pulls the rotor from its centered position. Many practitioners use positive values for the force constant and the position stiffness as a matter of convenience. In this case, the minus signs in Eq. 10 become plus signs.

The control current is determined by the measured displacement, y , and the characteristics of an adjustable sensor/compensator/amplifier transfer function:

$$G_{con}(s) = \frac{i_{con}}{y} \quad (13)$$

Substituting Eq. 11 into Eq. 10 gives

$$Fy = -k_F G_{con}(s)y - k_n y \quad (14)$$

FIGURE 13 Control magnetic circuit for one axis of a homopolar magnetic bearing

The characteristics of the control transfer function $G_{con}(s)$ are determined in order to stabilize the rotor/bearing system.

HOMOPOLAR BEARING In the homopolar bearing, a bias flux is used for linearization just as in the heteropolar bearing; however, the bias flux and control flux follow different paths. Additionally, the bias flux can be generated by either a permanent magnet (most common) or an electromagnetic coil. The use of a permanent magnet for bias reduces power consumption and makes the bearing more linear at large position offsets.

- a. *Magnetic control circuit*—The control circuit for one half of the homopolar bearing, shown in Figure 13, is across the top air gap, through the rotor, out the bottom air gap, and around the back iron.

When Eq. 1 is applied to this circuit, the result is similar to Eq. 2:

$$2Ni_{con} = B_{con}A \left(\frac{g}{\mu_o A} + \frac{g}{\mu_o A} + \frac{l_{stat}}{\mu_o \mu_{r,stat} A} + \frac{l_{rot}}{\mu_o \mu_{r,rot} A} \right) \quad (15)$$

Again, if the iron permeability is high relative to the air gap, this can be reduced to the following:

$$B_{con} = \frac{Ni_{con}\mu_o}{g} \quad (16)$$

- b. *Magnetic bias circuit*—The magnetic circuit equation for the bias circuit, shown in Figure 14, is

$$\frac{B_r l_m}{\mu_o \mu_{r,mag}} = B_{bias} A \left(\frac{g}{\mu_o A} + \frac{g}{\mu_o A} + \frac{l_m}{\mu_o \mu_{r,mag} A_m} \right) \quad (17)$$

Where B_r = residual induction of the magnet

l_m = axial length of the magnet

$\mu_{r,mag}$ = relative permeability of the magnet (≈ 1.0 – 1.05)

A_m = magnet cross-sectional area per quadrant

With the magnet permeability assumed to be 1.0, this can be reduced to

FIGURE 14 Bias magnetic circuit for one quadrant of a homopolar magnetic bearing

$$B_{bias} = \frac{B_r}{\frac{2g}{l_m} + \frac{A}{A_m}} \quad (18)$$

c. *Force calculation*—The basic force equation for an air gap is given by Eq. 4. In the homopolar bearing, the pole face covers a broader arc of the rotor than in the heteropolar bearing; therefore, the air gap force must be integrated over the surface to obtain the desired vector force, F_{top} . Both the front and back control stacks must also be included. The result is

$$F_{top} = 2C_g F_{gap}$$

Where:

$$C_g = \frac{2\sin(\theta_{a/2})}{\theta_a} \quad (19)$$

This result assumes negligible leakage and fringing and that the flux density is uniform in the air gap. Substituting from Eq. 4 into Eq. 19 gives

$$F_{top} = C_g \frac{B^2 A}{\mu_o} \quad (20)$$

If the saturation flux density, B_{sat} , of the iron material is used for B , Eq. 20 defines the load capacity as a function of pole area for a magnetic bearing.

d. *Linearization of the force/current characteristic*—The air gap flux density in the homopolar bearing is the superposition of the bias and control flux. The control coils and permanent magnet polarity are arranged such that when the control flux adds to the bias in the top air gaps, the control subtracts from the bias in the bottom air gaps. Thus the net vertical force is

$$F_y = F_{top} - F_{bot} = \frac{C_g A}{\mu_o} [(B_{bias} + B_{con})_{top}^2 - (B_{bias} - B_{con})_{bot}^2] \quad (21)$$

This can be reduced in a similar manner as before to produce

$$F_y = \frac{4C_g A}{\mu_o} B_{bias} B_{con} \quad (22)$$

Substituting from Eq. 16

$$F_y = \frac{4C_g AN}{g} B_{bias} i_{con} \quad (23)$$

Thus the control force is proportional to the control current as desired.

- e. *Force constant and negative stiffness*—The expression given in Eq. 10 for the heteropolar bearing also applies to the homopolar bearing:

$$F_y = -k_f i_{con} - k_n y \quad (24)$$

The definition of the force constant is

$$k_f = \frac{-4C_g AN B_{bias}}{g_0} = \text{force constant or current stiffness} \quad (25)$$

The expression for negative stiffness is not easily reducible to analytical form due to the complexity of the bias circuit. However, the existence of the permanent magnet in the bias flux path as a fixed and large reluctance improves the linearity of this bearing for off-center operation. Eqs. 13 and 14 for the heteropolar bearing apply to the homopolar bearing as well.

INSTALLATION AND TUNING

Mechanical Installation Magnetic bearings have the advantage that they can be set, by adjusting offsets in the controller, to center the rotor on the magnetic bearing stator, the catcher bearing, the seals, or any other mechanical reference in the pump. The rotor can even be offset vertically to cancel the effect of gravity, thus reducing static power requirements to near zero. Careful consideration is needed during design to decide which is the best approach.

The position sensors in the bearings can also be used to measure the clearances between the rotor and any physical stops such as a sealing ring, without disassembly.

Tuning The rotor dynamics analysis performed during the early design stage will be used to determine the initial controller compensation, which will have a transfer function matched to the pump requirements. During initial testing, this transfer function will have to be adjusted to match the as-built dynamics of the rotor and support structure.

Normally the rotor will be accurately modeled and little change will be needed. If there are shrink fits or bolted joints, there may be some stiffness variation from the theoretical model. This may require on-site controller compensation adjustment. However, the stator is often a complex structure, and adjustments may be needed to avoid the excitation of stator modes.

DIAGNOSTICS AND USER INTERFACE

Diagnostic Capabilities The controller, in order to function, must analyze a continuous stream of information on the shaft location in each of the five control axes, two for each radial bearing and one for the thrust bearing. This information can be accessed for external diagnostic use, as can the corresponding information on bearing current, from which can be inferred the bearing load. This diagnostic information can be a very useful source of information on the health of the pump, its mechanical components, and on the system it is operating in.

Interface Requirements The magnetic bearing system controller can also be interfaced with the plant control system with the following type of logic:

- No drive unit start without levitation
- No delevitation at speed
- Rotor offset and bearing load alarms
- Rotor offset and bearing load driver trips, with possible time delay

RELIABILITY AND MAINTENANCE

Bearing Cartridges As explained earlier, the reliability of the bearing stator and rotor components should be such as to provide lifetime service.

Controller The main life limiting component in the controller is likely to be the amplifier. In a redundant system, online replacement is possible without loss of levitation. In a non-redundant system, a preventative maintenance approach should be used for this component.

OPERATING EXPERIENCE

Multistage Boiler Feed Pump The multistage pump of Table 1 (refer to Figure 1) was installed as one of three otherwise identical pumps (two in parallel, one standby) in an electric utility generating plant (refer to Figure 2). The objective was to show that magnetic bearings would work in a typical field application of a pump of significant power level. This project took the first step of replacing the conventional bearings in this 610 hp (0.46 MW) eight stage centrifugal pump, which were outboard of the pump itself, and replacing them with heteropolar active magnetic bearings without any major design changes⁶. This was seen as the first of two steps, the second being a project where the bearings would be submerged in the operating fluid, allowing one seal system to be replaced⁸.

As with many magnetic bearing projects, the main lesson learned was that the transient bearing loads could not always be predicted ahead of time, and that the magnetic bearings gave very precise and important feedback of this information. Table 3 contains the design and field data. In this case, the 2500 lb (11 kN) transient load occurred when the plant underwent a suction pressure transient in which the available *NPSH* became so low that the first stage of this horizontally-opposed staging configuration (refer to Figure 1) apparently lost pressure rise completely⁶. The axial thrust of this stage was accordingly lost, destroying the intended axial hydrodynamic thrust balance of the pump. (See Sections 2.1 and 2.2.1.) Nevertheless, the conservative design of the thrust bearing enabled it to accommodate this load.

Single-Stage Process Pump The 800 hp (0.6 MW) single-stage double-suction process pump of size 8 × 26 (200mm × 660mm) of Table 1 was retrofitted with homopolar bearings⁷.

Closed-loop testing was conducted in the pump manufacturer's facility (see Figure 15). As indicated in Table 4, the results showed that a substantial operating margin exists for

TABLE 3 Operating experience with multistage pump

| Bearing | Expected Load, lb (kN) | | Design Load, lb (kN) | Actual Load, lb (kN) | |
|---------|------------------------|-------------|----------------------|----------------------|--------------|
| | Steady | Transient | | Steady | Transient |
| Radial | 280 (1.2) | 560 (2.5) | 800 (3.6) | 280 (1.2) | 580 (2.6) |
| Axial | 1,000 (4.4) | 2,000 (8.9) | 4,000 (17.8) | 1,100 (4.9) | 2,500 (11.1) |

FIGURE 15 Single-stage double-suction 10 × 26-size process pump [800 hp (0.6 MW)] with magnetic bearings. (Reference 7)

TABLE 4 Design and experimental loads for the single-stage pump

| Bearing | Expected Load, lb, (kN) | Design Load, lb (kN) | Actual Load, lb (kN) |
|---------|-------------------------|----------------------|----------------------|
| Radial | 953 (4.2) | 1,430 (6.4) | 1,450 (6.4) |
| Axial | 1,000 (4.4) | 4,000 (17.8) | 2,100 (9.3) |

the axial thrust bearing. Greater design capacity would provide the same margin with respect to radial loads.

The margins evident in Table 3 for the multistage pump may appear excessive, but until more operating knowledge about such pumps is acquired, it would appear that this degree of conservatism in designing magnetic bearings for pumps is merited.

COSTS

Backed by the vision of complete magnetic suspension and the attendant benefits, magnetic bearing technology has been proven and demonstrated in pumping machinery. However, the major deterrent to further application of this technology is cost. Retrofitting the magnetic bearings to the multistage pump described above cost at least twice the price of the pump itself, and this included the analog controller, which accounted for about a third of the retrofit cost. Digital controllers, a later development, are one third the size and cost of analog controllers; this has significantly reduced the overall cost. Much of this overall cost is in the engineering of the magnetic bearings, which includes matching this system to the rotordynamic characteristics of the pump. Use of the same system in quantity production would reduce the cost by up to 80 percent.

SECTION 2.2.7

SEALLESS PUMPS

FREDERIC W. BUSE
STEPHEN A. JASKIEWICZ

Sealless pumps are developed to eliminate the liquid leakage to the atmosphere that occurs from pumps that employ packing or mechanical seals. This leakage is usually toxic or dangerous to the environment. Sometimes the leakage is valuable. Eighty percent of the applications are for pressures below 200 lb/in² (13.8 bar) and below 250°F (120°C).

Sealless pumps are divided into two categories: magnetic drive pumps and canned motor pumps. The two categories compete against themselves in certain applications, but for the most part they each have their own market niche into which they are applied. Both have encapsulated inner driven mechanisms. On a magnetic drive pump (see Figure 5 in Section 2.2.7.1), the impeller is mounted to an inner magnet carrier. The inner and outer magnetic carriers are sealed by what is called a shell, which contains pump internal pressure. On a canned motor pump (see Figure 1 in Section 2.2.7.2), the impeller is mounted directly to the motor rotor. The atmospheric sealing element between the motor stator and rotor is called a liner or "can." Both magnetic drive and canned motor pumps use product lubricated bearings of compatible design and materials. These bearings are usually cooled and lubricated by the pump liquid.

The following sections describe both magnetic drive and canned motor pumps.

SECTION 2.2.7.1

MAGNETIC DRIVE PUMPS

FREDERIC W. BUSE

The principle of a magnetic drive pump is the elimination of the seal or packing in an overhung pump (Figure 1) and cutting the shaft in two at the seal location (Figure 2a). On the inner or wet end half of the shaft (Figure 2b), an inner magnet assembly (a) is placed on a shaft (b) supported by product lubricated bearings (c). On the other cut portion of the shaft, an outer magnet assembly (d) is placed on the power shaft (e). Between the inner and outer magnet assemblies, a static seal (f) isolates the shell (g) or diaphragm and the pumped liquid from the atmosphere. The magnetic flux from the outer magnet assembly drives the inner magnet assembly and impeller(s). The outer assembly is mounted directly to either its own bearing assembly in a frame housing (Figure 3) or motor shaft (Figure 4). Figure 5 shows a cross-section of a magnetic drive frame mounted pump.

Magnetics A magnetic circuit usually consists of two sets of permanent magnets and inner and outer conducting rings (Figure 6). The conducting rings can be cast iron, ductile iron, or a 400 series stainless steel.

Magnet Materials The first permanent magnets, developed in the 1940s, were made of aluminum-nickel-cobalt (AlNiCo) and used in small chemical pumps. Development of rare earth magnets in the 1980s made it possible to have a small power package that could drive larger pumps. The two types of rare earth materials commonly used are neodymium iron boron (NdFeB) and samarium cobalt (SmCo). The SmCo is four times stronger than AlNiCo. NdFeB, at 70°F (21°C), is 20% stronger than SmCo. The advantage of SmCo is the maximum service temperature of 550°F (288°C), almost twice that of NdFeB, which is 300°F (149°C). Figure 7 shows the strength versus temperature characteristics of the two materials. The cost of SmCo, however, is about twice that of NdFeB.

FIGURE 1 Pump with conventional bearing housing and mechanical seal (Flowserve Corporation)

The magnets have a maximum temperature at which they lose all magnetism in an irreversible process; the magnets do not regain magnetism as they cool. This temperature is the Curie temperature and is shown for each magnet material in Table 1.

TABLE 1 Operating and Curie temperatures for magnet materials

| Type of Magnet Material | Operating Temperature (°F/°C) | Curie Temperature (°F/°C) |
|-------------------------|---|---------------------------|
| AlNiCo | 660/305 | 800/425 |
| NdFeB | 250–300/120–137 (Depending on grade) | 600/310 |
| SmCo | 500–660/260–350 (Depending on grade) | 1300/700 |

Conduction Ring The amount of transmittal torque depends on the overall gap (Figure 8) between the poles of the magnets and the thickness of the conducting ring (Figure 9). If the thickness of the conducting ring is too small, it will become saturated with flux and the torque capability will be reduced.

B.

FIGURE 2 Comparison of typical mechanical seal arrangement and sealless pump drive configuration: a) arrangement for typical mechanical through casing cover; b) sealless drive configuration

FIGURE 3 Frame-mounted magnet drive arrangement

Gap The “overall gap” (Figure 10) is made up of the air gap, containment shell thickness, liquid gap, and encapsulation. Gap dimensions are based on the pressure requirement for the shell, the number of magnets (single or dual), and the material of the shell (metallic or nonmetallic) in the gap.

FIGURE 9 Rows of magnets

(A) NONMETALLIC COMPOSITE

(B) METALLIC

FIGURE 10A and B Encapsulation of magnets using nonmetallic composition and metallic clad

EXAMPLE Dimensions shown as in (mm)

| | | |
|--|--------------|--------------|
| Mean diameter (on radius dimensions) | 4.6 (117) | 6.0 (152.4) |
| Air gap minimum | .030 (0.762) | .045 (1.143) |
| Containment shell thickness: Hastelloy C | .040 (1.016) | .060 (1.524) |
| Polymer | .120 (3.048) | .150 (3.810) |
| Liquid gap | .035 (0.889) | .035 (0.889) |
| Encapsulation | .030 (0.762) | .030 (0.762) |
| Overall gap (basis Hastelloy C) | .135 (3.429) | .170 (4.318) |
| Overall gap (basis polymer) | .215 (5.461) | .260 (6.604) |

In the previous example, the same overall gap was maintained for polymer and Hastelloy C shells. This allows for interchangeability of the magnetic assemblies independent of shell material.

Transmittal Torque The torque transmitted by the magnets depends on the following:

- Flux density of the magnets, B_g
- Operating temperature of the magnets (which will change B_g)
- Length of the magnet poles, L
- Number of magnets per ring, M
- Mean ratios between the ID of the outer assembly magnets and OD of the inner assembly magnets, r
- Overall gap between the ID and OD of the magnets in the assembly, g
- A constant, K , which changes as a function of the specific design

Torque is determined from the following relationship, with appropriate units:

$$T = \frac{K \times B_g^2 \times L \times M \times r}{g}$$

For a given design type and configuration, the torque varies inversely as the square of the overall gap. Depending on costs and specific design construction, an assembly ring of magnets can have either one continuous length of magnets of a series of 1, 2, 3 or more rows of individual magnets.

TORQUE CAPABILITY

The ultimate torque is the static “breakaway torque.” To determine this, the magnet carriers are assembled so the inner carrier is locked in position. Then a torque is applied by bar and weights or by a torque wrench to the outer carrier. The torque value at which the two carrier assemblies break loose from each other radially—or “decouple”—is called the “breakaway torque.” The designer has to account for the driver start-up acceleration time, start-up torque, and an appropriate safety factor to apply to the breakaway torque to determine the allowable applied torque.

Table 2 gives examples of the torque capability of assemblies composed of NdFeB blocks of magnet 0.75 in wide \times 0.38 in high \times 1.125 in long (19 mm \times 9.65 mm \times 28.6 mm) with a 0.180 in (4.6 mm) thick conducting ring.

Basic Dimensioning of Magnet Blocks The magnet blocks can be made too long or too short, resulting in handling, magnet molding, or flux density problems. The ratio of the dimensions for magnet blocks for successful designs is as follows:

TABLE 2 Torque capability of magnet assemblies

| Mean Diameter in (mm) | Magnets/Row | Overall Gap in (mm) | Breakaway Torque ft-lb (N • m) |
|--------------------------|-------------|---------------------|-----------------------------------|
| 4.3 (109) | 12 | 0.240 (6.10) | 30 (40) |
| 6.0 (152) | 18 | 0.260 (6.60) | 60 (80) |

TABLE 3 Coefficients of thermal expansion (in/in/°F × 10⁻⁶)/(cm/cm/°C × 10⁻⁶)

| Magnet material | Parallel to Axis | Perpendicular to Axis |
|-----------------|------------------|-----------------------|
| NdFeB | 5 (9) | 9 (16.2) |
| SmCo | 20 (36) | 16 (28.8) |

- Block width is two to three times the thickness.
- Block length is three to five times the thickness.
- Doubling the block thickness will increase the strength by approximately 20%.

For reference: 1.0 in³ (16.387 cm³) of NdFeB per assembly at a mean diameter of 4.0 in (101.6 mm) with a 0.25 in (6.35 mm) overall gap produces approximately 7 ft-lb (9.5 N • m) of torque. A 3% reduction in flux density is equal to a 6% reduction in torque.

Characteristics of magnet material:

- Density: 0.273 lb/in³ (7.56 g/cm³)
- Tensile: 12 × 10³ lb/in² (844 kg/cm²)
- Compression: 110 × 10³ lb/in² (7.7 × 10³ kg/cm²)
- Flex stress: 36 × 10³ lb/in² (2.53 × 10³ kg/cm²)

Coefficients of thermal expansion are shown in Table 3.

Radial and Axial Magnet Forces The inner and outer carriers have to be restrained radially by bearings from contacting each other. In the example of “Torque Capability,” a single row of 18 magnets with a 6 in (152 mm) mean diameter, the radial force with magnets concentric is 40 lb (18 kgf). When the magnets are offset by .005 in (0.127 mm), the radial force is 55 lb (25 kgf) (Figure 9). When the magnets are against each other (no gap), the radial force is 80 lb (36 kgf).

In the previous example, it takes 60 lb (27 kgf) in an axial direction to separate a single row of concentric magnets and 180 lb (82 kgf) for three rows. It is strongly advisable that provisions be made for personnel to address these loads during assembly and disassembly of the carriers.

Encapsulation of Inner Carrier Magnetics Encapsulation can be accomplished with either metallic or polymer materials. The encapsulation of the inner magnet and conducting ring is probably the most expensive and extensive process in a magnetic drive sealless pump. After encapsulation, the carrier should be nondestructively tested to confirm 100% effectiveness.

The pros and cons of polymer encapsulation (Figure 10a) are as follows:

1. Limited to 250–300°F (120–150°C)
2. SmCo magnets are used because of the high exposure temperature when applying polymer over the magnets.

3. The overall gap is increased because of the required thickness of the polymer.
4. Magnets must be restrained mechanically on the conducting ring by adhesives or high-strength polymers around the magnets.
5. Polymers like PFA/PTFE or PEEK are more corrosive-resistant than most metals.
6. Production polymer construction is much less expensive than metallic construction.
7. Polymer tooling is expensive.

The pros and cons of metallic encapsulation (Figure 10b) are as follows:

1. Temperature rating can be 500°F (260°C).
2. Thickness of the encapsulation material over the magnets can be 0.030 in (0.76 mm).
3. Welding of the components can be conventional, electron beam, or laser. However, care must be taken with conventional welding to prevent the arc from jumping toward the magnet flux.
4. If castings are used for the inner carrier, porosity can be a problem.
5. Gassing of polymers from welding heat coming out of the seams can be a problem.
6. Adhesives are not required to keep the magnets in place at 3600 rpm with metallic encapsulation; the outer shield performs this function.

Encapsulation of Outer Carrier Magnets The magnets for the outer carriers do not have to be encapsulated (Figure 11). However, material like NdFeB has an infinity for water absorption that results in rusting and swelling. The magnets can then break loose and move in position relative to one another. It is highly recommended that they be encapsulated with an epoxy or metal sheathing for atmospheric protection and handling.

Construction The outer carrier can be a casting or fabrication. The carrier is attached to the power end shaft in the bearing housing (Figure 3) or directly to a motor shaft, which is then called *close coupled construction*. When attached to the bearing housing shaft, there is very little axial or radial load applied to the bearings. This lightly loaded condition can result in internal skidding of the rolling element bearings within their races, resulting in premature bearing failure. Therefore, it is best to preload the bearings with a spring to prevent skidding. This can be accomplished outside of the bearing by a spring-loading feature (Figure 11).

Containment Shell The containment shell shape and thickness depends on working pressure, material, and temperature. The shell thickness is usually uniform. To keep the

FIGURE 11 Inner and outer carrier

FIGURE 12 Shell ratio L/r for pressure

TABLE 4 Pressure capabilities of shells with various end shapes for the same thickness and material

| Shape | L/r | Allowable pressure—lb/in ² (kPa) | Ratio of allowable pressure to that for a flat plate |
|------------|-------|---|--|
| Flat | 533 | 9 (62) | 1.0 |
| Flat | 267 | 23 (158) | 2.55 |
| Elliptical | 28 | 113 (779) | 12.6 |
| Elliptical | 8 | 209 (1440) | 23.2 |
| Spherical | 1 | 815 (5620) | 90.5 |

length of the shell to a minimum, a square-ended shell can be used. However, unless the end of the shell is made extra thick, it would have a relatively low pressure capability. Therefore, an end shape which is elliptical or spherical is used to obtain higher pressure capability (Figure 12).

Examples of how allowable shell pressure varies with the shape of the end plate are shown in Table 4.

The classes of materials used for containment shells (Figure 11) include metals, polymers, and ceramics. The characteristics of containment shells of various materials are shown in Table 5. The main advantage of polymer or ceramic shells is that there are no eddy current losses. Therefore, cooling of the magnets is not required.

Eddy Currents Metallic or metallic-lined shells will produce eddy currents. Depending on the thickness of the shell, the eddy current losses (P_L) can amount to as much as 20% of the total power.

$$P_L = \frac{K \times T \times L \times N^2 B_g^2 D^3 M}{R}$$

where K = a constant, depending on the design

T = thickness of the shell

L = length of magnets (times the core of magnets)

N = speed, rpm

B_g = flux density of the magnets

D = mean diameter

M = number of sets of magnets

R = electrical resistivity, microhms per cm³ (electrical resistivity for various shell materials is given in Table 6)

TABLE 5 Characteristics of containment shells of various materials

| Material | Metal | Reinforced polymer | Ceramic | Metal with PTFE |
|---------------------------|------------------------------------|-----------------------------|-----------------------------|-------------------------|
| Construction | Welded or hydroformed | Injection molded | Set and fired | Spray coated |

TABLE 7 Effect of material selection on heat build-up

| Material of shell | Thickness-in (mm) | Time-minutes | kW | °F (°C) | °F/min (°C/min) |
|-------------------|-------------------|--------------|------|-----------|-----------------|
| AISI 316 | 0.43 (10.9) | Start | 0.40 | 80 (27) | — |
| AISI 316 | 0.43 (10.9) | 5.0 | 0.30 | 500 (260) | 100 (38) |
| Hastelloy C | 0.43 (10.9) | 0.5 | 0.24 | 170 (77) | 340 (171) |
| Hastelloy C | 0.43 (10.9) | 5.0 | 0.21 | 370 (188) | 74 (23) |

The effect of material selection on heat build-up is shown in Table 7. The tabulation shows the temperature rise of the air space inside a shell with only the outer carrier spinning around a metallic shell (no inner carrier in place) at 3550 rpm. The carrier has 12 magnets, 1.25 in (3.175 cm) long, with a mean diameter of 4.25 in (11.43 cm).

This illustrates the difference between AISI 316 and Hastelloy C shells at 3550 rpm. At 1750 rpm, the power loss for AISI 316 would be one-fourth that at 3550 rpm, which may not result in excess power consumption.

There are also axially laminated metal shells available that substantially reduce eddy current (I^2R) losses. These laminations work on the principle that when a shell length is

FIGURE 13 Dual containment

cut in half, the eddy current losses are reduced to one-fourth their original value. If the one-half shell length is cut in half again, the resulting pieces have eddy current losses one-sixteenth that of the original shell. A shell design made of segments sealed together to make a full-length shell will thus reduce total eddy current losses.

Dual Containment As a precaution against leakage due to a breach in the primary containment shell, a dual or double-containment arrangement can be used. This double layering of shells (Figure 13) usually consists of a combination of a nonmetallic and metallic shell. The pressure rating of the secondary shell is equal to that of the primary shell. It is designed to operate at least 48 to 120 hours after a breach in the primary shell occurs. A pressure monitor is inserted in the flange of the secondary shell to detect pressure buildup from primary shell leakage.

Bearings The internal shaft system of the pump is supported by one or more bearings. Some designs use a rotating shaft; others use a mandrel on which the bearings rotate. The bearing, which consists of a journal and bushing, is made of various materials, depending on the loads and pumpage (used for product lubrication). The bearing loads are from the weight of the components and hydraulic forces from the impeller and inner carrier. The impeller forces are both radial and axial.

Most magnetic drive sealless pumps are single-stage volute pumps that have the same radial bearing loads as comparable conventionally sealed pumps. The main difference with the sealless pump is that there is almost no overhang from the impeller to the first bearing. The load on the bearing, therefore, is almost equal to that of the impeller. In a conventionally sealed pump, the load on the radial bearing is almost twice that of the impeller. This can be seen by comparing Figures 1 and 5.

The axial load will depend on whether the impeller is enclosed or semi-open (Figure 14). Enclosed impellers usually have horizontal front rings and may also have a back ring or pump out vanes (POV). Semi-open impellers have no rings, but they usually employ scallops in the shroud to reduce the effective pressure area (Figure 15). Axial thrust force is further reduced by employing pump-out vanes (POV) or pump-out slots (POS) on the back shroud of the impeller to reduce the amount of pressure on the impeller back shroud.

The enclosed impeller can have less radial and axial load than a semi-open impeller. This is usually accomplished by employing back rings (14b). To ensure positive pumping in the lubrication flow path in magnetic drive pumps, POV-POS on an enclosed or semi-open impeller are recommended.

Liquids pumped in chemical or petroleum plants may have low viscosity, low specific gravity, or low specific heat. These characteristics can result in boundary lubrication rather than hydrodynamic lubrication of the product lubricated bearings. Therefore, bearings are selected using PV (pressure-velocity) values. Some limiting PV values for various bearing material combinations are shown in the following section on bearing materials.

FIGURE 14A through D Various enclosed and semi-open impeller configurations

A Semiopen Impeller with Full Back Shroud

B Partially Scalloped Semiopen Impeller

FIGURE 15A and B Semi-open impellers with a full back shroud and with a partially scalloped back shroud

Bearing Materials Table 8 shows PV values for various bearing journal and thrust face materials. When loads exceed a PV value of 150,000, the bearing should have an alignment compensator built in to correct for inaccuracies in perpendicularity, concentricity, and parallelism of parts.

When designing the bearing, thermal expansion and heat conductivity properties must be considered. Some designs have a temperature range of -300°F to $+750^{\circ}\text{F}$ (-150 to $+400^{\circ}\text{C}$). Table 9 lists bearing material characteristics to facilitate selection of the proper material for the intended application.

Particles For the softer bearing materials, the maximum particle size should be no more than 10% of the diametral clearance for a bearing with no grooves and no more than 20%

TABLE 8 PV values for various bearing journal and thrust face materials

| Bushing Materials | Journal/Thrust Face PV ($\times 10^3$)* |
|---|---|
| Carbon Graphite vs. AISI 316 | 150 |
| Carbon Graphite vs. Chrome Oxide Hardened Coating | 250 |
| Silicon Carbide vs. Hardened Coating | 250 |
| Silicon Carbide vs. Carbon Graphite | 300 |
| Silicon Carbide vs. Silicon Carbide | 500 |
| PEEK—Carbon-filled vs. Hardened Coating | 150 |
| Polyimide-carbon filled vs. Hard Coating | 150 |

P = Net load/projected area (minus area for slots), psi

V = Velocity at the shaft diameter or mean diameter of the thrust face in ft/min

*Note: Multiplying the PV values in the table by 2.1 will give values equal to P in kPa and V in m/min.

TABLE 9 Bearing material characteristics

| Material | Thermal Expansion (note 1) | Heat Conductivity (note 2) | Hardness (note 3) |
|-----------------------------------|-------------------------------|-------------------------------|----------------------|
| AISI 316 | 9.6 | 7.5 | 160 BHN |
| Hastelloy C | 6.7 | 71 | 170 BHN |
| Carbon graphite | 2.6 | 5 | 95 Vickers |
| Silicon carbide— self-sintered | 2.2 | 85 | 2400 Vickers |

| Aluminum oxide | | | 1800 Vickers |
| Chrome oxide | | | 1800 Vickers |

Note 1: in/in/°F $\times 10^{-6}$ (multiplied by 1.411 to get cm/cm/°C)

Note 2: BTU/hr/ft²/°F (multiply by 0.488 to get calories/hr/cm²/°C)

Note 3: $R_C \times 25$ = Vickers; BHN $\times 10$ = R_C

for a bearing with grooves. Polymers and graphites are much softer than silicon carbides or hard coatings, and they are not recommended for liquids with hard particles. Silicon carbide versus silicon carbide will grind up most particles. For particle concentrations of 50 parts per million (ppm) or less, particle hardness is generally not a factor in bearing performance.

Strainers of 100 mesh are recommended to reduce the amount and size of particles going through the flow path. These strainers are installed for internal or external injection. Remember: Particles that will pass through a 100 mesh screen may be as large as 0.006 in (0.15 mm), whereas nominal diametral bearing clearances of 0.002 in (0.05 mm) are common.

Note also that the bearing material combination of silicon carbide against silicon carbide or against carbon is electrically conductive.

Running Dry Most sealless pump failures occur because the pump system is not monitored and the pump is allowed to run dry. When this happens, the bearings will run dry. When the bearings run dry, hard, brittle bearing materials such as self-sintered silicon

carbide will fail within minutes. Graphite silicon carbide may run dry for as many as 10 to 20 minutes with no damage. The polymers, which are poor heat conductors, expand inwardly and seize against the mating surface. The graphites will also move inwardly, but they tend to wear rather than seize, which results in excessive clearances when the pump is stopped and cooled. One optional design uses Teflon strips that expand inwardly when the unit runs dry so the shaft runs on the Teflon rather than on the silicon carbide, thus helping to avoid bearing failure.

Another option is to employ an external circulating tank, with no external running parts, that will provide the bearings with external lubricating liquid should dry operation occur. This type of external tank system has allowed pumps to operate for two hours or more without incurring damage to the bearings.

Flow Path The amount and direction of flow for cooling of the magnets and lubrication of the bearings is critical to the operation of a sealless pump (Figure 16). It is preferable for the liquid to lubricate the bearings before being heated by the magnets. This reduces the possibility of vaporization of the liquid occurring at the thrust-bearing faces. The amount of liquid circulated through the system is usually between 1 and 8 gpm (4 and 30 l/min). It is usually channeled to the front and back bearings, the thrust bearing face, across the magnets, and to the impeller hub. Some manufacturers have computer programs that calculate the flow, pressure, and temperature of the cooling/lubricating flow at various critical locations along the flow path. These programs can also account for the effects of the liquid specific gravity, specific heat, and viscosity. The local pressure and temperature is used to determine the vapor pressure at that point to ensure that the liquid is not flashing. The programs can also calculate axial thrust and determine if the lubrication at the thrust bearing face is hydrodynamic or boundary. This is done at various flow rates, impeller diameters, and pump speeds.

The temperature rise of the liquid as it travels through the cooling-lubricating flow path depends to a great extent on the liquid's characteristics, such as specific gravity, specific heat, vapor pressure, and viscosity. With a nonmetallic shell on ambient water service, a typical temperature rise might be 1 to 2°F (0.5 to 1°C). For a metallic shell, with its much higher eddy current losses, the temperature rise could be as much as 8 to 12°F (4 to 7°C).

FIGURE 16 Magnetic sealless pump components for the internal flow system

FIGURE 17 Typical performance for a $1.5 \times 1.0 \times 6$ pump at 3550 rpm, comparing characteristics for sealless versus mechanical seal construction

Performance The head capacity curve of a typical two-pole speed sealless pump matches that of a conventionally sealed pump; however, the overall efficiency is lower. With a nonmetallic shell, the efficiency may be only about two points less at the best efficiency point flow rate, but as much as six points less at one-half the best efficiency point flow rate. When a metallic shell is used, the efficiency at best efficiency point flow rate may be as much as 8 to 12 points lower than a comparable pump with a mechanical seal (Figure 17).

APPLICATION ADVANTAGES OF SEALLESS PUMPS:

- No leakage to the environment
- No loss of valuable liquids
- Lower noise levels
- High suction pressure does not affect the axial thrust
- Can handle liquids from 0 to 4 toxicity rating
- Because of no leakage, there is much less chance of a fire
- Easier to obtain construction permits and permits for continued operation
- Less external piping required

APPLICATIONS THAT SHOULD BE REVIEWED BEFORE SEALLESS PUMPS ARE APPLIED:

- Dirty liquids
- High temperature
- Liquids that solidify
- Viscous liquids above 200 centipoise
- Oversize drivers that can cause decoupling during acceleration
- Cavitation of liquid in the impeller eye that can result in excess thrust
- Excessive entrained gas

SECTION 2.2.7.2

CANNED MOTOR PUMPS

STEPHEN A. JASKIEWICZ

A canned motor pump (CMP) is a combination of a centrifugal pump and a squirrel cage induction motor built together into a single hermetically sealed unit (see Figure 1). The pump impeller (A) is normally of the closed type and is mounted on one end of the rotor shaft that extends from the motor section into the pump casing. The rotor (B) is submerged in the fluid being pumped and is therefore “canned” to isolate the motor parts from contact with the fluid. The stator (C) is also “canned” to isolate it from the fluid being pumped. Bearings (D) are submerged in system fluid and are, therefore, continually lubricated.

The canned motor pump has only one moving part, a combined rotor-impeller assembly that is driven by the magnetic field of an induction motor. A portion of the pumped fluid is allowed to recirculate through the rotor cavity to cool the motor and lubricate the bearings. A self-cleaning filter can be provided, on pumps having external circulation, to filter the recirculation fluid before it enters the bearing section of the motor. The stator windings and rotor armature are protected from contact with the recirculating fluid by a corrosion resistant, non-magnetic, alloy liner (E) that completely seals or “cans” the stator winding.

Modifications to the recirculation flow system are available to allow canned motor pumps to be used in any application including fluids up to 1000°F (538°C), volatile liquids, and liquids with solids.

BASIC DESIGN

Stator Assembly The stator assembly of canned motor pumps (see Figure 2) consists of a set of one or three-phase windings (A). Stator laminations (B) are constructed of low-silicon grade steel. Laminations and windings are mounted inside the cylindrical stator band (C). End bells (D and E), welded to the stator band, close off the ends of the stator

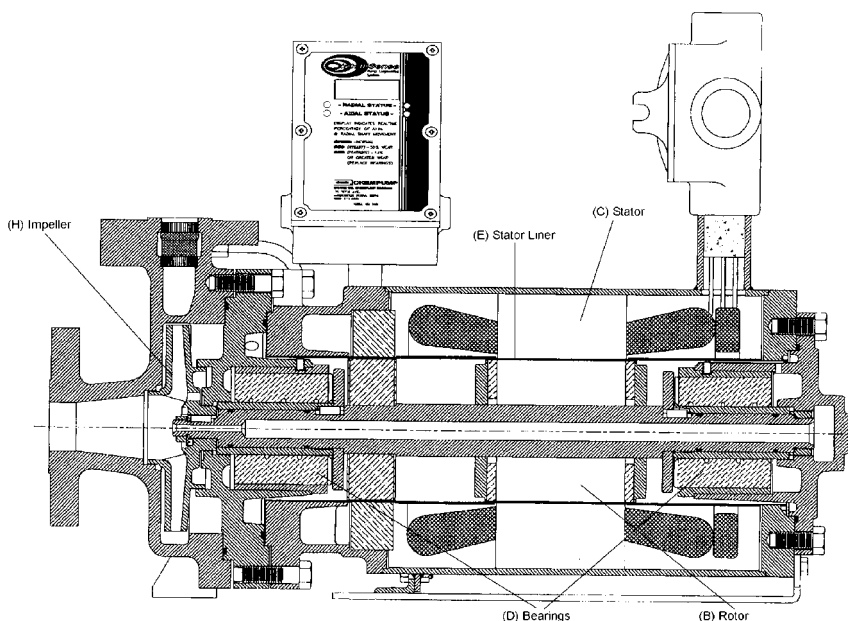

FIGURE 1 Typical canned motor pump

assembly. The stator liner (F) is supported on the outside diameter by the steel lamination of the motor. Back-up sleeves (G) are provided to strengthen those areas of the stator liner not supported by the stator laminations. The stator liner is, in effect, a cylindrical “can” placed in the stator bore and welded to the rear end bell and front end bell shroud to hermetically seal off the windings from contact with the liquid being pumped. Terminal leads (H) from the windings are brought out through a pressure tight lead connector (I) mounted on the stator band and terminated in a standard connection box.

Motors are either designed and manufactured specifically for use in canned motor pumps or components of conventional motor are modified. A variety of motor insulation types is available ranging from temperature limits of 266°F (130°C) to above 482°F (250°C).

Because the pump and motor are one unit, the complete assembly must be tested and approved for explosion-proof applications. Explosion-proof pumps are rated as either Class 1, Group D, Division 1 or Class 1, Group C & D, Division 1 locations. It is not uncommon to operate canned motor pumps with variable speed drive controllers.

Rotor Assembly The rotor assembly is a squirrel cage induction rotor constructed and machined for use in canned motor pumps (see Figure 3). It consists of a machined corrosion resistant shaft (A), laminated core (B) with copper or aluminum bars and end rings, corrosion resistant end covers (C), and a corrosion resistant can (D). Various methods are used to attach the impeller to the motor shaft (E).

The rotor end covers are welded to the shaft and to the rotor can that surrounds the outside of the rotor, thus hermetically sealing off the rotor core from contact with the liquid being pumped.

Some manufactures offer replaceable shaft sleeves (F) and axial thrust surfaces (G) for longer service life and ease of maintenance.

Bearings Only two bearings are required for canned motor pumps. These bearings are normally cooled and lubricated by the pumped fluid; therefore, they must be compatible

FIGURE 2 Stator assembly

FIGURE 3 Rotor assembly

with the process fluid. A multitude of materials is available such as various grades of carbon graphite, silicon carbide, aluminum oxide, and many polymers. Bearing selection is dependent on the compatibility with the process fluid, amount of solids present, and pumping temperature.

A hydrodynamic bearing is the most common type of bearing used. The bearings can be either stationary or rotating with the rotor assembly. In either case, the fluid passes between the bearing and shaft journal, resulting on the rotating assembly running on a thin film of liquid, not the journal and bearing. Most bearings have helical grooves in the inside diameter to increase the flow of process fluid through the journal area, thereby decreasing the temperature of the bearings.

Internal Clearances The determination of the overall gap between the stator windings and the rotor armature is paramount in the design and operation of the pump. The wider the distance between the iron of the motor winding and the rotor armature, the less efficient the motor becomes. The material of construction of the stator liner and rotor sleeve

also effects motor efficiency. Stainless steels and Hastelloy are the most common materials used for stator liners and rotor sleeves. Although stainless steel is less expensive, Hastelloy C has higher corrosion resistance, is a stronger material, and offers lower electrical losses. Motor efficiency in canned motor pumps is not only important for energy cost considerations, but also for the amount of heat input to the recirculation fluid.

The stator liner (a wetted, pressure boundary component) ranges in thickness between 0.010 to 0.040 in (0.254 to 1.016 mm). For high-pressure applications, the liner remains at the same thickness, but the outside diameter is supported by the motor laminations and by back up sleeves located on both sides of the motor. Canned motor pumps have been designed to withstand working pressures up to 5,000 lb/in² (345 bar) with 0.015 in (0.381 mm) stator liners and heavy walled back-up sleeves.

The rotor armature (a wetted component) is also protected from the process fluid by a sleeve and two end covers. The thickness of the rotor sleeve ranges from 0.010 to 0.25 in (0.254 to 6.35 mm). The radial running clearance between the rotating motor armature and the stationary stator liner is usually about 0.020 in (0.508 mm). The total diametral clearance can range from 0.040 to 0.075 in (1.016 to 1.905 mm), or higher, depending on the manufacturer's design.

Secondary Containment Canned motor pumps offer a level of safety and process fluid containment unavailable with any other type of pump. Positive, secondary containment of the process fluid is a built-in feature with canned motor pumps when the motor lead wires are housed in a pressure retaining lead seal. In case of a failure of the primary containment shell (stator liner), the outer stator band becomes a secondary containment vessel, preventing the process fluid from entering the environment.

The outer stator band is far removed from the rotation element, making it impossible for the rotating element to make contact. When secondary containment is required, the stator band assembly should be designed and tested to the same pressure and temperature rating as the pump.

PRINCIPLE OF OPERATION

Flow Path Most canned pumps, when pumping relatively clean fluids, will channel a small portion of the process fluid through the motor section. This fluid cools and lubricates the bearings and removes heat generated by the induction motor. The circulation path can be either external or internal to the pump. With external circulation (see Figure 4), the recirculation fluid is piped outside of the pump, through a filter, and then into the motor section of the unit. The filter assembly (see Figure 5) is self-cleaning and located in the discharge flange of the pump. Pumps having internal circulation have the recirculation contained within the pump. Filtering the recirculation liquid is not available with internal circulation.

In either external or internal circulation, the flow path is from the high pressure area of the pump (pump discharge or pump chamber at the tip of the impeller) returning to the low pressure area (near the hub or eye of the impeller). The amount of liquid recirculated through the motor section ranges from 2 to 16 gpm (7.5 to 60 l/m).

Many recirculation flow path modifications are available to allow a canned motor pump to pump any type of fluid. When pumping volatile fluids, the motor section can be pressurized by an auxiliary impeller located on the rotor. The recirculation fluid, which normally returns to the eye of the impeller, is channeled to the pressurized section of the liquid end, increasing the pressure in the motor section. This design allows a volatile fluid to remain liquid even with a temperature increase caused by motor heat (see Figure 6). Another method to handle fluids near their boiling point is to reverse the recirculation flow path. Instead of returning the heated liquid back to the eye of the impeller, the recirculation liquid is removed from the pump and returned to the suction vessel.

High temperature and slurry applications can be handled by canned motor pumps by isolating the bearings from the pumped fluid. The recirculating fluid in the motor section

FIGURE 4 External circulation flow path

FIGURE 5 Self-cleaning filter assembly

is used for lubrication of the bearings and cooling of the motor. This fluid remains in the motor section and is circulated through the rotor cavity by an auxiliary impeller, which is an integral part of the rotor assembly. The fluid in the motor section is forced across the rotor and through the bearings, after which it flows through a heat exchanger. The heat exchanger is cooled by water or a suitable heat transfer fluid (see Figure 7). The motor section can be backflushed with a clean, cooled liquid when handling slurry.

In Hydraulic Institute Standard ANSI/HI 5-1-5.6, Figure 5.9 provides an excellent description of various recirculation flow plans for sealless pumps.

Thrust Balance Because most canned motor pumps use hydrodynamic bearings, the rotating assembly is allowed to float axially. This movement is known as “end play” and is defined as the movement of the rotor, in the axial direction, between the forward and

FIGURE 6 Pressurized circulation

FIGURE 7 Isolated motor section

FIGURE 8 Automatic hydraulic thrust balance

rear contact points (normally the thrust bearings). Many canned motor pumps incorporate a principle of hydraulic thrust balance to position the rotation assembly between the forward and rear mechanical contact points. Based on hydraulic principles, automatic thrust balance is accomplished by the pressure of the pumped fluid. Pressure chambers are designed either within the pump chamber using the movement of the impeller or rear of the pump controlling the rate of return of the process fluid.

Figure 8 illustrates hydraulic thrust balance within the pump casing. Balance chambers are located on the front and rear of the impeller. When a change in axial load changes the position of the impeller, either forward or rear, there is an equalizing change of hydraulic pressure in the balance chambers, which immediately returns the rotation assembly into a balance position.

Pressure-Temperature Profile The single most important consideration in the application and successful operation of canned motor pumps is bearing environment control. The process fluid cools and lubricates the bearings and removes the heat generated by the motor. The bearings must remain in a liquid state to provide adequate bearing lubrication.

A number of variables must be considered when considering the state of the recirculation fluid. These variables include vapor pressure, specific heat, specific gravity, viscosity, pump efficiency, motor efficiency, motor load, recirculation flow rate, and the recirculation flow system. A vapor pressure curve versus temperature of the process fluid is also necessary. Figure 9 illustrates heat balance equations necessary to determine the temperature rise of the fluid within the motor section. Figures 10a, b, and c show pressure and temperature profiles for a specific fluid based on the heat balance equations within a canned motor pump modified for pressurized circulation. If the flow rate varies, a new profile should be calculated for each design condition.

A pressure-temperature profile should be calculated for any application where there is doubt concerning the condition of the recirculation fluid.

Installation The installation of a canned motor pump can be much less costly than a conventionally sealed unit because canned motor pumps do not require special base-plates or mounting pads. In fact, many canned motor pumps are stilt-mounted or bolted directly into the system piping. There is only one shaft in a canned motor pump; therefore, alignment of the pump to the driver is not necessary and pump orientation is not critical. The unit can be mounted either horizontally or vertically, with the pump casing

up or down. The sleeved bearings are located in the bearing housing. Alignment of the bearings is accomplished by a register fit between the bearing housings and the stator assembly.

Diagnostics Some canned motor pump manufacturers have developed diagnostic systems that monitor the condition of the internal wear surfaces of the pump. Because the

FIGURE 10A Pressurized circulation—points of reference

FIGURE 10B Pressurized circulation pressure profile

rotating components of the pump are not visible, even the direction of rotation can not be easily determined.

Advanced diagnostic systems indicate both axial and radial wear continuously. Continuous wear indication allows the pump user to trend the wear of the pump and schedule standard wear parts replacement long before a major failure occurs.

Remote outputs are also available on these diagnostic systems. These outputs include either a digital or analog signal, or a relay designed to shut down the pump—or signal an alarm—when a certain amount of bearing wear has occurred.

FIGURE 10C Pressurized circulation temperature rise

The diagnostic systems available today are perhaps the most significant advancement in the technology of sealless pumps. Figure 11, rotor position output data, illustrates the type of information available when using digital output linked to a data collection system.

SECTION 2.3

CENTRIFUGAL PUMP PERFORMANCE

2.3.1

CENTRIFUGAL PUMPS: GENERAL PERFORMANCE CHARACTERISTICS

C. P. KITTREDGE
PAUL COOPER

DEFINITIONS

Nomenclature Many of the quantities involved in this subsection are also dealt with in Section 2.1. Therefore, a single nomenclature that applies to both sections appears at the beginning of Section 2.1. Differences in notation exist for some of these quantities as a result of the coexistence of different traditions and pump cultures, so the nomenclature shows the equivalence in each case. An example is the use in this subsection of “c” and “w” to denote absolute and relative velocity respectively, whereas the NASA system of capital letters V and W is employed in Section 2.1.

Units The units used in this subsection are as defined in the nomenclature unless specifically noted in the text. In particular, the primary units for this subsection are those of the U.S. Customary System (USCS). A distinction in USCS usage in this subsection is that the pound force (lbf) is represented simply as “lb”. In keeping with the commentary on SI units in the front matter of this handbook, conversions to SI units are given throughout this subsection, or the actual equivalent SI values are given in parentheses.

However, the number appearing in parentheses after the USGS value of specific speed n_s is the equivalent value of the universal specific speed Ω_s . Note that the value of specific speed corresponding to the best efficiency point (BEP) operating conditions of the pump is the value of interest and is often used to identify the impeller geometry involved.

Volume Flow Rate Abbreviated to “flow rate” and known traditionally as “pump capacity” Q , this is the volume of liquid per unit time delivered by the pump. In USCS units, Q is expressed in U.S. gallons per minute or USgpm, for which the abbreviation “gpm” is

FIGURE 1A through C Elevation datum for defining pump head (Hydraulic Institute ANSI/HI 2000 Edition Pump Standards, Reference 27)

used. (1 US gallon = 231 in³.) For very large pumps, the units ft³/sec are used. The consistent SI units m³/s are implied when an SI value of Q is—unless the numerically convenient liters per second (l/s) are specifically called out.

Datum for Pump Head As defined in Eq. 3 and Figure 1 of Section 2.1, the total head has components of pressure, velocity, and elevation Z (or Z_e). Because pump head H (more precisely ΔH) is the difference of the total heads evaluated at the discharge flange d and the suction flange s respectively, the elevation of the datum from which Z is measured cancels out. However, for purposes of identification, computing NPSH, and so on, the standard datum as shown in Figure 1 is used.

The standard datum for horizontal-shaft pumps is a horizontal plane through the centerline of the shaft (Figure 1a). For vertical-shaft pumps, the datum is a horizontal plane through the entrance eye of the first-stage impeller (Figure 1b) if single suction or through the centerline of the first stage impeller (Figure 1c) if double suction. Because pump head is the difference between the discharge and suction heads, it is not necessary that the standard datum be used, and any convenient datum may be selected for computing the pump head.

Power In USCS, the pump output is customarily given as liquid horsepower (lhp) or as water horsepower if water is the liquid pumped. It is given by

$$lhp = \frac{QH(\text{sp. gr.})}{3960} \quad (1)$$

where Q is in gallons per minute, H is in feet, and sp. gr. is specific gravity. If Q is in cubic feet per second, the equation becomes

$$lhp = \frac{QH(\text{sp. gr.})}{8.82} \quad (2)$$

In SI, the power P in watts (W) is given by

$$P = 9797QH (\text{sp. gr.}) \quad (3)$$

where Q is in cubic meters per second and H is in meters.

When Q is in liters per second and H is in meters

$$P = 9.797QH (\text{sp. gr.}) \quad (4)$$

Efficiency The pump efficiency η is the liquid horsepower divided by the power input to the pump shaft. The latter usually is called the brake horsepower (bhp). The efficiency may be expressed as a decimal or multiplied by 100 and expressed as percent. In this subsection, the efficiency will always be the decimal value unless otherwise noted. Some pump driver-units are so constructed that the actual power input to the pump is difficult or impossible to obtain. Typical of these is the “canned” pump for volatile or dangerous liquids. In such case, only an *overall efficiency* can be obtained. If the driver is an electric motor, this is called the *wire-to-liquid efficiency* or, when water is the liquid pumped, the *wire-to-water efficiency*.

CHARACTERISTIC CURVES

Pump with Non-Viscous Flow and Zero Slip The basic shapes of centrifugal pump performance characteristics arising from various geometries can be ascertained and compared without the necessity of evaluating the slip. (Illustrated in Figure 15 of Section 2.1, the slip phenomenon is explained in the related discussion¹.) For this purpose, one employs the artifice of non-viscous flow through an impeller with an infinite number of blades having infinitesimal thickness and that therefore produce neither structural (geometric) nor flow (boundary layer) blockage. The result is the ideal head for no slip or blockage H_e as given by Eq. 5 (cf. Eq. 15b of Section 2.1):

$$H_e = \frac{u_2 c_{u2}}{g} - \frac{u_1 c_{u1}}{g} \quad (5)$$

The velocity components in Eq. 5 can be seen in the velocity diagrams of Figure 2, slip being neglected. Generally the inlet swirl term is small, and Eq. 5 can be approximated by

$$H_e \cong \frac{u_2 c_{u2}}{g} \quad (6)$$

As shown in Figure 2b, the absolute velocity vector c may be resolved into the meridional, or radial, velocity c_m and the peripheral velocity c_u . From the geometry of the figure

$$c_{u2} = u_2 - \frac{c_{m2}}{\tan \beta_2} \quad (7)$$

which, substituted into Eq. 6, gives

FIGURE 2A and B Velocity diagrams for radial-flow impellers, neglecting slip and blockage

FIGURE 3 Head-versus-flow rate characteristics for non-viscous, zero-slip impeller flow

$$H_e = \frac{u_2^2}{g} - \frac{u_2 c_{m2}}{g \tan \beta_2} \quad (7)$$

Neglecting leakage flow, the meridional velocity c_m must be proportional to the capacity Q . With the additional assumption of constant impeller speed, Eq. 8 becomes

$$H_e = k_1 - k_2 Q \quad (8)$$

in which k_1 and k_2 are constants, with the value of k_2 dependent on the value of the vane angle β_2 . Figure 3 shows the H_e -vs- Q characteristics for the three possible conditions on the vane angle at exit β_2 . The second right-hand term in Eq. 5 may be treated in like manner to the foregoing and included in Eqs. 8 and 9. The effect on Figure 3 would be to change

the value of $H_e = u_2^2/g$ at $Q = 0$ and the slopes of the lines, but all head-flow rate characteristics would remain straight lines.

Viscous Flow with Slip The real flow situation involves friction losses in an impeller with a finite number of relatively widely spaced blades. Thus, slip occurs, reducing the exit flow angle $\beta_{f,2}$ below that of the blade β_2 , (or, more precisely, $\beta_{b,2}$) which in turn reduces c_{u2} (cf. Figure 15 of Section 2.1). Therefore, the ideal head H_i drops below H_e . Moreover, losses and recirculation occur to cause additional deviation of pump head H from H_e . While CFD flow analysis can be employed to predict H with fair accuracy², lesser means, such as one-dimensional analysis, require experienced correlation and calibration skills to make such predictions. Therefore, many engineers commonly depend on testing and empirical modification of test results on the exact or similar geometry to make the final determination of the performance characteristics of a pump. This effort involves constant-speed plots of data as shown in the example of Figure 4.

Pumps are designed to operate at the point of best efficiency. The head, power, and flow rate at best efficiency, often called the *normal* values, are indicated in this subsection by H_n , P_n , and Q_n respectively. Sometimes a pump may be operated continuously at a flow rate slightly above or below Q_n . In such case, the actual operating point is called the *rated* or *guarantee* point if the manufacturer specified this capacity in the guarantee. It is unusual to operate a pump continuously at a flow rate at which the efficiency is much below the maximum value. Apart from the unfavorable economics, the pump may be severely damaged by continued off-design operation, as described later.

Backward-Curved Blades, $\beta_2 < 90^\circ$ Figure 4 shows the characteristics of a double-suction pump with backward-curved blades, $\beta_2 = 23^\circ$. The impeller discharged into a single volute casing, and the specific speed was $n_s \approx 2200$ ($\Omega_s \approx 0.8$) at best efficiency. At shut-off ($Q = 0$), Eq. 8 predicts H_e to be 374 ft (114 m), whereas the pump actually developed about 210 ft (64 m), and this head remained nearly constant for the range $0 < Q < 1000$ gpm (63 l/s). For $Q > 1000$ gpm (63 l/s), the head decreased with increasing capacity but not in the linear fashion predicted by Eq. 9. At best efficiency, where $Q_n = 3200$ gpm (202 l/s), Eq. 8 predicts $H_e = 281$ ft (86 m), whereas the pump actually developed $H_n = 164$ ft (50 m).

FIGURE 4 Typical pump characteristics, backward-curved blades (ft $\times 0.3048 =$ m; hp $\times 745.7 =$ W; gpm $\times 0.06309 =$ l/s)

Radial Blades, $\beta_2 = 90^\circ$ Large numbers of radial-blade pumps are used in many applications, from cellar drainers, cooling-water pumps for internal combustion engines, and other applications where low first cost is more important than high efficiency to highly engineered pumps designed for very high heads. The impellers are rarely more than 6 in (15 cm) in diameter, but the speed range may be from a few hundred to 30,000 rpm or more. The casings usually are concentric with the impellers and have one or more discharge nozzles that act as diffusers. The impellers usually are open, with three or more flat blades. The clearance between blades and casing is relatively large for easy assembly. Such pumps exhibit a flat head-capacity curve from shutoff to approximately 75% of best efficiency flow rate, and beyond this flow the head-flow curve is steep. The pumps develop a higher head, up to 8000 ft (2400 m) per stage, than pumps with backward-curved blades, but the efficiency of the former usually is lower. (See also Subsection 2.2.1.)

Figure 5 shows the characteristics of a pump as reported by Rupp.³ The impeller was fully shrouded, $D = 5.25$ in (13.3 cm), and fitted with 30 blades of varying length. The best efficiency, $\eta = 55\%$, was unusually high for the specific speed $n_s = 475$ (0.174), as may be seen from Figure 6. The head-flow curve showed a rising (unstable) characteristic for $0 < Q < 25$ gpm (1.6 l/s) and a steep characteristic for $Q > 25$ gpm (1.6 l/s).

Figure 7 shows the characteristics of a pump as reported by Barske.⁴ The impeller was open, $D \approx 3$ in (7.6 cm), and fitted with six radial tapered blades. The effective β_2 may have been slightly greater than 90° due to the taper. At 30,000 rpm, the best efficiency was more than 35% at $n_s = 355$ (0.130), which is much higher than for a conventional pump of this specific speed and capacity (Figure 6). The head-flow curve showed a nearly flat characteristic over most of the usable range, as predicted by Eq. 8, but the head was always lower than H_c . The smooth concentric casing was fitted with a single diffusing discharge nozzle. When two or more nozzles were used, the head-flow curves showed irregularities at low flow rates and became steep at high flow rates.

Manson⁵ has reported performance characteristics for jet engine fuel pumps having straight radial blades in enclosed impellers. The head curves showed unstable characteristics at low flow rates and steep characteristics at higher flow rates. The best efficiency reported was 54.7% for an impeller diameter of 3.300 in (8.382 cm) and speed $n = 28,650$ rpm.

Forward-Curved Blades, $\beta_2 > 90^\circ$ Pumps with forward-curved blades have been proposed,⁶ but the research necessary to achieve an efficient design appears never to have been carried out. Tests have been made of conventional, backward-curved-blade, double-suction pumps with the impellers mounted in the reversed position but with rotation correct for the volute casing. As tested, these pumps therefore had forward-curved blades.

FIGURE 7 Pump characteristics, radial blades ($\text{lb/in}^2 \times 6.894 = \text{kPa}$; $\text{gpm} \times 0.06309 = \text{l/s}$) (Reference 4)

Table 1 shows the pertinent results for six different pumps. Both flow rate and efficiency were drastically reduced, and there was only a modest increase in head for five of the six pumps. The sixth pump showed a 38% increase in head over that obtained with the impeller correctly mounted. Published estimates^{7,8} of the head-flow curves to be expected from reversed impellers predict an unstable characteristic at the low end of the flow rate range and a steep characteristic at the high end of the range.

PERFORMANCE EFFECTS

Classification of Curve Shapes A useful method for comparing characteristics of pumps of different specific speeds is to normalize on a selected operating condition, usually best efficiency. Thus,

TABLE 1 Effects of reversed mounting of impeller

| Number of stages | Specific speed per stage n_s (Ω_s) | Percent of normal shutoff head | Percent of normal values at best efficiency | | | |
|------------------|---|--------------------------------|---|-----------|-------|------------|

$$q = \frac{Q}{Q_n} \quad h = \frac{H}{H_n} \quad p = \frac{P}{P_n} \quad (10)$$

where the subscript n designates values for the best efficiency point. Figures 8, 9, and 10 show approximate performance curves normalized on the conditions of best efficiency and for a wide range of specific speeds as defined in Table 2. These curves are applicable to pumps of any size because absolute magnitudes have been eliminated. In Figure 8, curves 1 and 2 exhibit a *rising head* or *unstable* characteristic where the head increases with increasing flow rate over the lower part of the flow rate range. This may cause instability at heads greater than the shutoff value, particularly if two or more pumps are operated in parallel. Curve 3 exhibits an almost constant head at low flow rates and is often called a *flat* characteristic. Curves 4 to 7 are typical of a *steep* or *stable head* characteristic, in which the head always decreases with increasing flow rate. Although the shape of the head-flow curve is primarily a function of the specific speed, the designer has some control through selection of the vane angle β_2 , number of impeller vanes n_b , and capacity coefficient $\phi = c_{m2}/u_2$, as described in Section 2.1 (see also Figure 2). For pumps having a single-suction specific speed approximately 5000 (1.83) and higher, the power is at its maximum at shutoff and decreases with increasing flow rate. This may require an increase in the power rating of the driving motor over that required for operation at normal capacity.

Efficiency The efficiency η is the product of three component efficiencies (defined in Section 2.1):

$$\eta = \eta_m \eta_v \eta_h \quad (11)$$

The mechanical efficiency η_m accounts for the bearing, stuffing box, and all disk-friction losses including those in the wearing rings and balancing disks or drums if present. The volumetric efficiency η_v accounts for leakage through the wearing rings, internal labyrinths, balancing devices, and glands. The hydraulic efficiency η_h accounts for liquid friction losses in all through-flow passages, including the suction elbow or nozzle, impeller, diffusion vanes, volute casing, and the crossover passages of multistage pumps. Figure 11 shows an estimate of the losses from various sources in double-suction single-stage pumps having at least 12-in (30-cm) discharge pipe diameter. Minimum losses and hence maximum efficiencies are seen to be in the vicinity of $n_s \approx 2500$ (0.91), which agrees with Figure 6.

Effects of Pump Speed Increasing the impeller speed increases the efficiency of centrifugal pumps. Figure 7 shows a gain of about 15% for an increase in speed from 15,000 to 30,000 rpm. The increases are less dramatic at lower speeds. For example, Ippen⁹ reported about 1% increase in the efficiency of a small pump, $D = 8$ in (20.3 cm) and $\eta_s = 1992$ (0.73), at best efficiency, for an increase in speed from 1240 to 1880 rpm. Within limits, the cost of the pump and driver usually decreases with increasing speed. Abrasion

FIGURE 11 Power balance for double-suction pumps at best efficiency (Reference 12)

and wear increase with increasing speed, particularly if the liquid contains solid particles in suspension. The danger of cavitation damage usually increases with increasing speed unless certain suction requirements can be met, as described later.

Effects of Specific Speed Figures 6 and 11 show that maximum efficiency is obtained in the range $2000 (0.73) < n_s < 3000 (1.10)$, but this is not the only criterion. Pumps for high heads and small flow rates occupy the range $500 (0.18) < n_s < 1000 (0.37)$. At the other extreme, pumps for very low heads and large flow rates may have $n_s = 15,000 (5.49)$ or higher. For given head and flow rate, the pump having the highest specific speed that will meet the requirements probably will be the smallest and least expensive. However, Figure 9 of Section 2.1 shows that it will run at the highest speed and be subject to maximum wear and cavitation damage, as previously mentioned.

Effects of Clearance

WEARING-RING CLEARANCE Details of wearing-ring construction are given in Subsection 2.2.1. Schematic outlines of two designs of rings are shown in Figure 12. The L-shaped construction shown in Figure 12a is very widely used with the close clearance between the cylindrical portions of the rings. Leakage losses increase and pump performance

FIGURE 12A and B Typical wearing rings

TABLE 3 Effects of increased wearing-ring clearance on centrifugal pump performance

| Specific speed n_s (Ω_s) | Design head, ft (m) | Ring clearance, % of normal value | Percent of values at shutoff with normal ring clearance | | | Percent of values at best efficiency with normal ring clearance | | |
|--|------------------------|--------------------------------------|--|------|------|--|-------|-------|
| | | | Q | H | P | η | H_0 | P_0 |
| 2100 (0.77) | 63 (19.2) | 178 | 100 | 98.3 | 98.9 | 99.4 | 97.0 | 100 |

falls off as the rings wear. Table 3 shows some of the effects of increasing the clearance of rings similar to Figure 12a.

The labyrinth construction shown in Figure 12b has been used to increase the leakage path without increasing the axial length of the rings. If the pressure differential across these rings is high enough, the pump shaft may take on lateral vibrations with relatively large amplitude and long period, which can cause serious damage. One remedy for these vibrations is to increase clearance 2 in Figure 12b relative to clearance 1, at the expense of an increased leakage flow. High-pressure breakdown through plain rings may cause vibration,¹⁰ but this is not usually a serious problem. It is considered good practice to replace or repair wearing rings when the nominal clearance has doubled. The presence of abrasive solids in the liquid pumped may be expected to increase wearing-ring clearances rapidly.

VANE-TIP CLEARANCE Many impellers are made without an outer shroud and rely on close running clearances between the vane tips and the casing to hold leakage across the vane tips to a minimum. Although this construction usually is not used with pumps having specific speeds less than about 6000 (2.20), Wood et al.¹¹ have reported good results with semi-open impellers at $1800 (0.66) \leq n_s \leq 4100 (1.50)$. It appears that both head and efficiency increase with decreasing tip clearance and are quite sensitive to rather small changes in clearance. Reducing the tip clearance from about 0.060 in (1.5 mm) to about 0.010 in (0.25 mm) may increase the efficiency by as much as 10%. Abrasive solids in the liquid pumped probably will increase tip clearances rapidly.

MODIFICATIONS TO IMPELLER AND CASING

Diameter Reduction To reduce cost, pump casings usually are designed to accommodate several different impellers. Also, a variety of operating requirements can be met by changing the outside diameter of a given radial impeller. Eq. 6 shows that the head should be proportional to $(nD)^2$ provided that the exit velocity triangles (Figure 2b) remain similar before and after cutting, with w_2 always parallel to itself as u_2 is reduced. This can be achieved if the impeller meridional exit area $A_{m,2}$ is the same before and after cutting—and if the flow angle $\beta_{f,2}$ (Figure 15, Section 2.1) also stays the same. [$\beta_{f,2}$ would stay the same if the blade angle $\beta_2 (= \beta_{h,2})$ does, the difference being due to slip velocity V_s that should also scale down with D .] For radial discharge impellers, area $A_{m,2}$ equals $\pi D b_2$ (minus blade and boundary layer blockage) and requires that b_2 increase as D decreases. This is typical of many impellers—as is constancy of β_2 over the cutting range—and, together with Eqs. 27–33 of Section 2.1, leads to the so-called “affinity laws” for predicting performance:

$$\frac{Q_1}{Q_2} = \frac{n_1 D_1}{n_2 D_2} \quad (12a)$$

$$\frac{H_1}{H_2} = \frac{n_1^2 D_1^2}{n_2^2 D_2^2} \quad (12b)$$

$$\frac{P_1}{P_2} = \frac{n_1^3 D_1^3}{n_2^3 D_2^3} \quad (12c)$$

which apply only to a given impeller with altered D and constant efficiency but *not* to a geometrically similar series of impellers. The assumptions on which Eqs. 12 were based are rarely if ever fulfilled in practice, so exact predictions by the equations should not be expected. A common example is the low- n_s radial discharge impeller with parallel radial hub and shroud profiles over most of the path from inlet to exit (Figure 6). Here, $A_{m,2}$ decreases with cutting, and H falls more than would be predicted by Eq. 12b. [This type of impeller is often found in multistage pumps, particularly those in which the designer, driven by cost reduction goals, has minimized a) the axial length occupied by each stage and b) the number of stages, thereby pushing down the n_s of the individual stage to the point that a tolerable sacrifice in efficiency results.]

RADIAL DISCHARGE IMPELLERS Impellers of low specific speed may be cut successfully provided the following items are kept in mind:

1. The angle β_2 may change as D is reduced, but this usually can be corrected by filing the blade tips. (See the discussion on blade-tip filing that follows.)
2. Tapered blade tips will be thickened by cutting and should be filed to restore the original shape. (See the discussion below on blade-tip filing.)
3. Bearing and stuffing box friction remain constant, but disk friction should decrease with decreasing D .
4. The length of flow path in the pump casing is increased by decreasing D .
5. Because c_{m1} is smaller at the reduced capacity, the inlet triangles no longer remain similar before and after cutting, and local flow separation may take place near the blade entrance tips.
6. The second right-hand term in Eq. 5 was neglected in arriving at Eqs. 12, but it may represent a significant decrease in head as D is reduced.
7. Some blade overlap should be maintained after cutting. Usually the initial blade overlap decreases with increasing specific speed, so the higher the specific speed, the less the allowable diameter reduction.
8. Diameter reductions greater than from 10 to 20% of the original full diameter of the impeller are rarely made.

Most of the losses are approximately proportional to Q^2 , and hence to D^2 by Eq. 12. Because the power output decreases approximately as D^3 , it is reasonable to expect the maximum efficiency to decrease as the wheel is cut, and this often is the case. By Eq. 12 and the n_s -definition (Eq. 38a of Section 2.1), the product $n_s D$ should remain constant so the specific speed at best efficiency increases as the wheel diameter is reduced (Table 4).

The characteristics of the pump shown in Figure 13 may be used to illustrate reduction of diameter at constant speed. Starting with the best efficiency point and $D = 16\frac{5}{16}$ in (41.4 cm), let it be required to reduce the head from $H = 224.4$ to $H' = 192.9$ ft (68.4 m to 58.8 m) and to determine the wheel diameter, capacity, and power for the new conditions.

Because the speed is constant, Eqs. 12 may be written

$$H = k_H Q^2 \quad \text{and} \quad P = k_P Q^3 \quad (13)$$

where k_H and k_P may be obtained from the known operating conditions at $D = 16\frac{5}{16}$ in (41.4 cm). Plot a few points for assumed capacities and draw the curve segments as shown by the solid lines in Figures 13b and 13c. Then, from Eqs. 12

$$D' = D\sqrt{H'/H} \quad Q' = Q\sqrt{H'/H} \quad P' = P(H'/H)^{3/2} \quad (14a)$$

$$D' = D(Q'/Q) \quad H' = H(Q'/Q)^2 \quad P' = P(Q'/Q)^3 \quad (14b)$$

from which $D = 15\frac{1}{8}$ in (38.4 cm), $Q = 3709$ gpm (234 l/s), and $P' = 215.5$ hp (160.7 kW). In Figure 13, the initial conditions were at points A and the computed conditions after cutting at points B. The test curve for $D = 15\frac{1}{8}$ in (38.4 cm) shows the best efficiency point *a* at a lower flow rate than predicted by Eqs. 14, but the head curve satisfies the predicted values very closely. The power prediction was not quite as good. Table 4 and Figure 13 give actual and predicted performance for three impeller diameters. The error in predicting the best efficiency point was computed by (predicted value minus test value) (100)/(test value). As the wheel diameter was reduced, the best efficiency point moved to a lower flow rate than predicted by Eq. 14 and the specific speed increased, showing that the conditions for Eqs. 12 to hold were not maintained.

Wheel cutting should be done in two or more steps with a test after each cut to avoid too large a reduction in diameter. Figure 14 shows an approximate correction, given by Stepanoff,¹² that may be applied to the ratio D'/D as computed by Eqs. 12 or 14. The accuracy of the correction decreases with increasing specific speed. Figure 15 shows a correction proposed by Rüttschi¹³ on the basis of extensive tests on low-specific-speed pumps. The corrected diameter reduction ΔD is the diameter reduction $D - D'$ given by Eqs. 14 and multiplied by k from Figure 15. The shaded area in Figure 15 indicates the range of scatter of the test points operating at or near maximum efficiency. Near shutoff the values of k were smaller and at maximum flow rate the values of k were larger than shown in Figure 15. Table 5 shows the results of applying Figures 14 and 15 to the pump of the preceding example.

There is no independent control of Q and H in impeller cutting, although Q may be increased somewhat by underfiling the blade tips as described later. The flow rate and power will automatically adjust to the values at which the pump head satisfies the system head-flow curve.

MIXED-FLOW IMPELLERS Diameter reduction of mixed-flow impellers is usually done by cutting a maximum at the outside diameter D_o and little or nothing at the inside diameter D_i , as shown in Figure 16. Stepanoff¹⁴ recommends that the calculations be based on the average diameter $D_{av} = (D_i + D_o)/2$ or estimated from the blade-length ratio FK/EK or GK/EK in Figure 16d. Figure 16 shows a portion of the characteristics of a mixed-flow impeller on which two cuts were made as in Figure 16b. The calculations were made by Eqs. 14 using the mean diameter

$$D_m = \sqrt{(D_o^2 + D_i^2)/2}$$

instead of the outside diameter in each case. The predictions and test results are shown in Figure 16 and Table 6. It is clear that the actual change in the characteristics far exceeded

TABLE 4 Predicted characteristics at different impeller diameters on a radial-flow pump

the predicted values. Except for the use of the mean diameters, the procedure was essentially the same as that described for Figure 13, and all points and curves are similarly labeled. The corrections given in Figure 14 would have made very little difference in the computed diameter reductions, and those of Figure 15 were not applicable to impellers having specific speeds greater than $n_s = 2000$ (0.73). In this case, the product $n_s D_m$ did not remain constant and the maximum efficiency increased as D_m was reduced. Although the

^a $D'/D = 15.125/16.3125 = 0.927$; by Figure 14, corrected $D'/D = 0.935$. Corrected $D' = (0.935)(16.3125) = 15.25$ in.

^b $D'/D = 14.000/16.3125 = 0.858$; by Figure 14, corrected $D'/D = 0.874$. Corrected $D' = (0.874)(16.3125) = 14.26$ in.

^c $D - D' = 16.3125 - 15.125 = 1.1875$; by Figure 15, $K \cong 0.6$ at $n_s = 1,953$. Corrected $D - D' = (0.6)(1.1875) = 0.7125$ and corrected $D' = 16.3125 - 0.7125 = 15.60$ in.

^d $D - D' = 16.3125 - 14.000 = 2.3125$; by Figure 15, $K \cong 0.6$ at $n_s = 1,953$. Corrected $D - D' = (0.6)(2.3125) = 1.3875$ and corrected $D' = 16.3125 - 1.3875 = 14.93$ in.

changes in diameter were small, the area of blade removed was rather large for each cut. The second cut eliminated most of the blade overlap.

The characteristics of mixed-flow impellers can be changed by cutting, but very small cuts may produce a significant effect. The impellers of propeller pumps are not usually subject to diameter reduction.

Shaping Blade Tips If the discharge tips of the impeller blades are thick, performance usually can be improved by filing over a sufficient length of blade to produce a long, gradual taper. Chamfering, or rounding, the discharge tips may increase the losses and should never be done. Reducing the impeller diameter frequently increases the tip thickness.

FIGURE 16A through C Diameter reduction of mixed-flow impeller (ft $\times 0.3048$ = m; in $\times 2.540$ = cm; gpm $\times 0.06309$ = l/s; hp $\times 0.7457$ = kW)

OVERFILING This is shown at *B* in Figure 17, and the unfiled blade is shown at *A*. Usually there is little or no increase in the blade spacing d before and d_F after filing, so the discharge area is practically unchanged. Experience indicates that any change in the angle β_2 due to overfiling usually produces a negligible change in performance.

UNDERFILING This is shown at *C* in Figure 17. If properly done, underfiling will increase the blade spacing from d to d_f and hence the discharge area, which lowers the average meridional velocity c_{m2} , at any given flow rate Q . The angle β_2 usually is increased slightly. Figure 18A and Eq. 6 show that the head and consequently the power increase at the same flow rate. The maximum efficiency usually is improved and may be moved to a higher flow rate. At the same head, Figure 18B shows that both c_{m2} and the flow rate will increase. The change both in the area and in C_{m2} may increase the flow rate by as much as 10%. Table 7 shows the results of tests before and after underfiling the impeller blades of nine different pumps. In general, they confirm the foregoing predictions based on changes in area and in the velocity triangles.

FIGURE 17 Underfiling and overfiling of blade tips

FIGURE 18 Discharge velocity triangles for underfired blades (neglecting slip)

INLET BLADE TIPS If the inlet blade tips are blunt, as shown at *D* in Figure 17, the cavitation characteristics may be improved by sharpening them, as shown at *E*. In this case overfiling increases the effective flow area, which reduces c_{m1} for a given flow rate. If more area is needed, it may be advantageous to cut back part of the blade and sharpen the leading edge. Overfiling tends to increase β_1 , which is incompatible with a decrease in c_{m1} (Figure 19). The increase in β_1 increases the angle of attack of the liquid approaching the blade. In Figures 2 and 19, w_1 is tangent to the centerline of the blade at entrance and w_0

TABLE 7 Changes in performance when impeller blades are underfiled

| Specific speed n_s | Ω_s | No. of stages | Impeller diameter D_2 in (cm) | Change in blade spacing d_F/d | $\frac{H_F - H}{H}$ % ^b | Changes at best efficiency point after filing, % | | | | |

FIGURE 19 Effect of overfiling at inlet on the velocity triangle just inside the blades

is the velocity of the approaching liquid as seen by an observer moving with the blade. The angle δ between w_0 and w_1 is the angle of attack, which increases to δ_F after overfiling. Although the increase in δ tends to increase the opportunity for the liquid to separate from the low-pressure face of the blade, this disadvantage usually is outweighed by the improvement that results when c_{m1} is reduced.*

*The distinction between a true velocity diagram formed just upstream of the impeller blades and the triangles shown just inside the blades in Figure 19 should be noted. w_1 in this figure is shown aligned with the blade, having undergone an adjustment in direction via incidence from that of the approaching w_0 . Only by plotting the velocity diagram just upstream of this point can one determine the true value of the circumferential component c_{u1} of the absolute velocity being delivered to the impeller by the upstream piping, vanes, and so on. It is this delivered value of c_{u1} that must be used in computing input or ideal head of the impeller (Eq. 15b, Section 2.1 or, neglecting slip, Eq. 6 of this subsection). Thus w_0 is properly the true w_1 vector and should be understood as such (see Section 2.1).

CASING TONGUE The casing tongue or cutwater forms part of the throat of the discharge nozzle of many volute casings (Figure 20a, Section 2.1). Frequently the throat area is small enough to act as a throttle and reduce the maximum flow rate otherwise obtainable from the impeller. Cutting back the tongue increases the throat area and increases the maximum flow rate. The head-versus-flow rate characteristic is then said to *carry out farther*. Shortening the discharge nozzle may increase the diffusion losses a little and result in a slightly lower efficiency.

CAVITATION

The formation and subsequent collapse of vapor-filled cavities in a liquid due to dynamic action are called *cavitation*. The cavities may be bubbles, vapor-filled pockets, or a combination of both. The local pressure must be at or below the vapor pressure of the liquid for cavitation to begin, and the cavities must encounter a region of pressure higher than the vapor pressure in order to collapse. Dissolved gases often are liberated shortly before vaporization begins. This may be an indication of impending cavitation, but true cavitation requires vaporization of the liquid. Boiling accomplished by the addition of heat or the reduction of static pressure without dynamic action of the liquid is arbitrarily excluded from the definition of cavitation.

When a liquid flows over a surface having convex curvature, the pressure near the surface is lowered and the flow tends to separate from the surface. *Separation* and *cavitation* are completely different phenomena. Without cavitation, a separated region contains turbulent eddying liquid at pressures higher than the vapor pressure. When the pressure is low enough, the separated region may contain a vapor pocket that fills from the downstream end,¹⁵ collapses, and forms again many times each second. This causes noise and, if severe enough, vibration. Vapor-filled bubbles usually are present and collapse very rapidly in any region where the pressure is above the vapor pressure. Knapp¹⁶ found the life cycle of a bubble to be on the order of 0.003 s.

Bubbles that collapse on a solid boundary may cause severe mechanical damage. Shuttler and Mesler¹⁷ photographed bubbles that distorted into toroidal-shaped rings during collapse and produced ring-shaped indentations in a soft metal boundary. The bubbles rebounded following the initial collapse and caused pitting of the boundary. Pressures on the order of 10^4 atm have been estimated¹⁸ during collapse of a bubble. All known materials can be damaged by exposure to bubble collapse for a sufficiently long time. This is properly called *cavitation erosion*, or *pitting*. Figure 20 shows extensive damage to the suction side of pump impeller vanes after about three months' operation with cavitation. At two locations, the pitting has penetrated deeply into the $\frac{3}{8}$ -in (9.5-mm) thickness of stainless steel. The unfavorable inlet flow conditions, believed to have been the cause of the cavitation, were at least partly due to elbows in the approach piping. Modifications in the approach piping and the pump inlet passages reduced the cavitation enough to extend impeller life to several years.¹⁹

It has been postulated that high temperatures and chemical action may be present at bubble collapse, but any damaging effects due to them appear to be secondary to the mechanical action. It seems possible that erosion by foreign materials in the liquid and cavitation pitting may augment each other. Controlled experiments²⁰ with water indicated that the damage to metal depends on the liquid temperature and was a maximum at about 100 to 120°F (38 to 49°C). Cavitation pitting, as measured by weight of the boundary material removed per unit time, frequently increases with time. Cast iron and steel boundaries are particularly vulnerable. Controlled experiments have shown that cavitation pitting in metals such as aluminum, steel, and stainless steel depends strongly on the velocity of the fluid in the undisturbed flow past the boundary. On the basis of tests of short duration, Knapp¹⁵ reported that damage to annealed aluminum increased approximately as the sixth power of the velocity of the undisturbed flow past the surface. Hammitt²¹ found a more complicated relationship between velocity and damage, as shown in Figure 21. It seems clear that after cavitation begins, it will increase rapidly with increasing velocities. Frequently the rate of pitting accelerates with elapsed time. Comprehensive discussions of cavitation and erosion together with additional references are given by Preece.²²

FIGURE 20 Impeller damaged by cavitation (Demag Delaval, Reference 19)

FIGURE 21 Cavitation damage exponent versus test time for several materials in water (Reference 21)

Centrifugal pumps begin to cavitate when the suction head is insufficient to maintain pressures above the vapor pressure throughout the flow passages. The most sensitive areas usually are the low-pressure sides of the impeller vanes near the inlet edge and the front shroud, where the curvature is greatest. Axial-flow and high-specific-speed impellers without front shrouds are especially sensitive to cavitation on the low-pressure

sides of the vane tips and in the close tip-clearance spaces. Sensitive areas in the pump casing include the low-pressure side of the tongue and the low-pressure sides of diffusion vanes near the inlet edges. As the suction head is reduced, all existing areas of cavitation tend to increase and additional areas may develop. Apart from the noise and vibration, cavitation damage may render an impeller useless in as little as a few weeks of continuous operation. In multistage pumps cavitation usually is limited to the first stage, but Kovats²³ has pointed out that second and higher stages may cavitate if the flow is reduced by lowering the suction head (submergence control). Cavitation tends to lower the axial thrust of an impeller. This could impair the balancing of multistage pumps with opposed impellers. A reduction in suction pressure may cause the flow past a balancing drum or disk to cavitate where the liquid discharges from the narrow clearance space. This may produce vibration and damage resulting from contact between fixed and running surfaces.

Net Positive Suction Head (NPSH) Several criteria exist for establishing the *NPSH* of a pump. These are connected with a) inception of cavitation, b) loss of hydraulic performance, and c) protecting the pump against cavitation erosion or damage. These are defined and found as follows:

- a. *Inception NPSH*. Cavitation can be completely prevented so long as the static pressure within the pump is everywhere greater than the vapor pressure of the liquid. This can be achieved if the *NPSH* (also called h_{wv}), defined in Section 2.1 as the total head of the pumped liquid at the pump inlet datum or suction flange above that vapor pressure, is sufficiently large. The value of *NPSH* that achieves this is called *NPSH_i*, namely, the “inception *NPSH*.”
- b. *Performance NPSH*. In a typical *NPSH*-test at constant speed n and flow rate Q , a substantial reduction of *NPSH* below *NPSH_i* is usually necessary to reach the value that produces an identifiable drop in performance—usually 3% of pump stage total pressure rise or pump head. This value is called the “required *NPSH*,” *NPSHR* or *NPSH_{3%}*. Table 1 in Section 2.1 provides empirical correlations for *NPSH_{3%}* for common pumps and inducers. Other criteria for *NPSH_{3%}* will be given further on. The domains of cavitation within a pump are widespread at this condition, and experience shows that a head drop in the neighborhood of 3% must occur in order to obtain a repeatable value of *NPSHR* on test¹². Lower percentages have been demanded by users, but they invariably give rise to a large scatter in the measured *NPSHR* for even small variations in any of the test variables.

It used to be thought throughout the pump community that there are no cavities or bubbles present at zero percent head drop due to cavitation activity within a pump. In recent decades, however, it has been proven through many observations that not only is the head drop equal to zero at inception (where $NPSH = NPSH_i$), it remains so for an enormous range of lesser *NPSH*-values over which extensive bubble activity is observed. In fact, *NPSH_i* is commonly from two to five times the magnitude of the *NPSHR* that is associated with any noticeable drop in pump head. At the 3% (or lesser percentage) head drop condition, actual observations of the cavitating flow show the cavities to extend all the way from the leading edge of each blade to the throat formed by the leading edge of the next blade²⁴. In the face of these learnings, it is evident that to demand a test for the *NPSH* required for a head drop of much less than 3% usually causes only needless misunderstandings and expenditure of time and money.

- c. *Damage-Limiting NPSH or Life NPSH*. If it is desired to substantially reduce or eliminate cavitation activity within the pump, an acceptance test should be conducted wherein the cavitating flow can be observed visually²⁵. This is indeed a serious issue if the pump energy level is high enough (and therefore the inlet pressure) for the collapsing cavities to do damage (as in Figure 20; see also Section 2.1). In such a case, “*NPSH_{3%}*” has virtually no meaning; rather, the truly *required NPSH* or “*NPSHR*” is that *larger* value which satisfactorily limits the extent of this visually observed cavitation within the pump or pump model²⁶.

Therefore, the *available NPSH* at the installation must be at least equal to the *required NPSH* if the above consequences are to be avoided—be they significant loss of

FIGURE 22 Definition sketch for computing NPSH

pump head (that is, loss of hydraulic performance) or damage due to collapsing cavities. Increasing the available *NPSH* above the required value provides a margin of safety against unpredictable variations of conditions, including transient behavior. Figure 22 and the following symbols will be used to compute the available *NPSH*:

p_a = absolute pressure in atmosphere surrounding gage, Figure 22

p_s = gage pressure indicated by gage or manometer connected to pump suction at section *s-s*; may be positive or negative

p_t = absolute pressure on free surface of liquid in closed tank connected to pump suction

p_{vp} = vapor pressure of liquid being pumped corresponding to the temperature at section *s-s* (if liquid is a mixture of hydrocarbons, p_{vp} must be measured by the *bubble point* method)

h_f = lost head due to friction in suction line between tank and section *s-s*

V = average velocity at section *s-s*

Z, Z_{ps} = vertical distances defined by Figure 22; may be positive or negative

γ = specific weight of liquid at pumping temperature

It is satisfactory to choose the datum for small pumps as shown in Figures 1 and 22, but with large pumps, the datum should be raised to the elevation where cavitation is most likely to start. For example, the datum for a large horizontal-shaft propeller pump should be taken at the highest elevation of the impeller-blade tips. The available *NPSH* is given by

$$h_{sv} = \frac{p_a - p_{vp}}{\gamma} + \frac{p_s}{\gamma} + Z_{ps} + \frac{V^2}{2g} \quad (15)$$

or

$$h_{sv} = \frac{p_t - p_{vp}}{\gamma} + Z - h_f \quad (16)$$

Consistent units must be chosen so that each term in Eqs. 15 and 16 represents feet (or meters) of the liquid pumped. Equation 15 is useful for evaluating the results of tests. Equation 16 is useful for estimating available $NPSH$ during the design phase of an installation. In Eq. 15, the first term represents the height of a liquid barometer, h_b , containing the liquid being pumped and the sum of the remaining terms represents the suction head h_s ; that is, the total head H (Eq. 3, Section 2.1) evaluated at the suction flange S in Figure 22. Therefore

$$h_{sv} = h_b + h_s \quad (17)$$

Usually, a positive value of h_s is called a *suction head* and a negative value of h_s is called a *suction lift*.

Many pumps draw cold water from reservoirs exposed to atmospheric pressure, so the suction lift is limited if there is to be a reasonable value of h_{sv} ($= NPSH$) available at the pump suction flange or port. In normal practice, rather small values of suction lift or suction head are encountered in many installations, so one can depend on the value of h_{sv} being a substantial portion of h_b —say about 60% or 20 ft (6m) of water column. Recognizing that the suction specific speed capability S of most pumps falls within a rather small range has led to charts of recommended operating speeds such as those in Section 9.10 or the speed recommendations of Figure 23 for condensate pumps for varying amounts of $NPSH$ available. In fact, $S = 8500$ ($\Omega_{ss} = 3.11$) is recommended by the Hydraulic Institute²⁷. S ($= N_{ss}$) and Ω_{ss} are defined in Eqs. 41 and 42 of Section 2.1. The relationship of suction-specific speed to other suction parameters is treated further on.

Cavitation Tests In addition to the constant- Q tests for $NPSHR$ that were described in the foregoing review of the various $NPSH$ -criteria, one can establish the curve of performance $NPSH$ versus flow rate by varying the $NPSH$ available and seeing how much flow

FIGURE 23 Capacity (flow rate) and speed limitations for condensate pumps with shaft through eye of impeller (ft $\times 0.3048$ = m; gpm $\times 0.06309$ = l/s) (adapted from Hydraulic Institute ANSI/HI 2000 Edition Pump Standards, Reference 27)

FIGURE 24 Test of a 1.5-in (3.81-cm) single-stage pump at 3470 rpm, on water, 70°F (21°C) ($\text{ft} \times 0.3048 = \text{m}$; $\text{gpm} \times 0.06309 = \text{l/s}$) (Reference 12)

rate Q the pump can handle. This is illustrated in Figure 24, wherein a different head curve is found for each value of $NPSH$. For each such curve, as Q is increased, there is a point at which the head departs from the next one of higher $NPSH$. This, then, is the Q for which the given $NPSH$ is that required to maintain head, essentially $NPSH_{3\%}$. At higher flow rate, performance is lost, each head curve possessing a “cutoff” flow rate. References 27 and 28 may be consulted for details of test procedures.

Thoma Cavitation Parameter σ All the terms in Eqs. 15 to 17 may be made dimensionless by dividing each by the pump head H . The resulting parameter

$$\sigma = \frac{h_{su}}{H} \quad (18)$$

has proven to be useful especially for high-specific speed pumps and turbines. The loading on the blades of a variable-pitch propeller, and therefore the minimum suction-side static pressure, is directly connected to the head developed. As this head increases with increasing blade setting angle, the loading increases, the minimum pressure drops, and the $NPSHR$ goes up. Hence an identifiable limiting value of σ is found to exist for such a machine. σ -limits are presented for a range of specific speeds in Figure 25.

Performance- $NPSH$ data are sometimes given in terms of σ ; for example, Rüttschi¹³ presents the effect of pump hydraulic efficiency on $NPSH$ in these terms, a consistently higher value of σ being required for pumps with lower efficiency (Figure 26).

Suction-Specific Speed For pumps in which the eye diameter of the impeller is smaller than that at exit, the pressures on the suction-sides of the blades that are associated with most of the head addition are in a region of higher pressure than in the vicinity of the eye. Thus Wislicenus²⁹ was able to decouple the eye from outer diameter of the pump (where most of the head is generated in a radial-flow machine) and show that only the eye geometry determines performance- $NPSH$ and not the magnitude of the head created by the impeller. He demonstrated that for most centrifugal pumps (except the propellers just described), there is a small range of suction specific speed—from which the performance- $NPSH$ can be determined. As in defined in Section 2.1, this parameter is defined as follows:

$$S = \frac{N\sqrt{Q}}{(h_{su})^{3/4}} \quad (19)$$

Note that Q = half the discharge of a double-suction impeller when computing S . Equations 18 and 19 and the definition of n_s may be combined to yield

FIGURE 25 Cavitation limits of centrifugal and propeller pumps (Flowserve Corporation)

FIGURE 26 Cavitation parameter σ versus specific speed for different efficiencies ($\Omega_s = n_s/2733$) (Reference 13)

FIGURE 27 Commercial pumps applicable to zero suction head. Suction specific speed $S = 8000$ ($\Omega_{ss} = 2.93$). For centrifugal impellers, $n_s = 1,000$ –5,000 ($\Omega_s = 0.4$ –1.8); mixed-flow, 5,000–9,000 (1.8–3.3); propeller, 9,000–13,000 (1.3–4.8).

$$\sigma = \left(\frac{n_s}{S} \right)^{4/3} \quad (20)$$

$$n_s = S(\sigma)^{3/4} \quad (21)$$

Figure 25 shows lines of constant S . For most pumps, $7500 < S < 11,000$ ($2.7 < \Omega_{ss} < 4.0$), $S = 8500$ (3.11) being recommended by the Hydraulic Institute ANSI/HI 2000 Pump Standards (Reference 27). Higher values may apply to special designs or service conditions, such as an inducer ahead of the first-stage impeller. For a given specific speed, the lower the value of S , the safer the pump against cavitation. Experience with large European pumped storage installations has shown that cavitation effects began at $S \approx 6000$ (2.2), and this value is recommended for large pumps. Figure 27 shows a summary of data and formulas that may be useful with commercial pumps.

German practice differs considerably from that in the United States in computing suction specific speed. Pfleiderer¹ defined a hub correction k as

$$k = 1 - \left(\frac{d_h}{D_o} \right)^2 \quad (22)$$

where d_h = the hub diameter and D_o = the diameter of the suction nozzle, in any consistent units. The suction specific speed S_G is defined as

$$S_G = \frac{(n/100)^2 Q}{k h_{sv}^{3/2}} \quad (23)$$

where n is measured in rpm, Q in cubic meters per second per impeller inlet, and h_{sv} in meters of liquid pumped. It follows that

$$S = 5164 \sqrt{S_G k} \quad (24)$$

NPSH for Liquids Other Than Cold Water Field experience, together with carefully controlled laboratory experiments, has indicated that pumps handling hot water or cer-

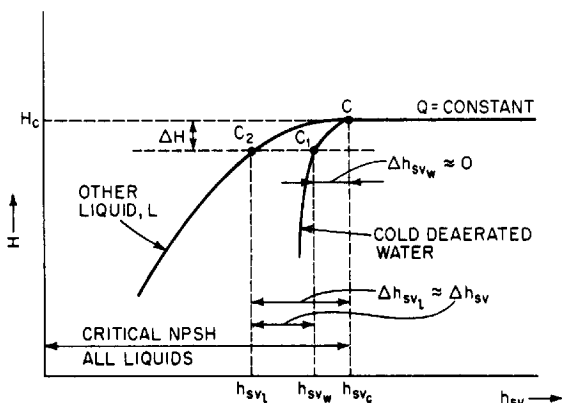

FIGURE 28 Cavitation tests with different liquids at constant speed and constant flow rate (Reference 34)

tain liquid hydrocarbons may be operated safely with less *NPSH* than would normally be required for cold water. This may lower the cost of an installation appreciably, particularly in the case of refinery pumps. A theory for this has been given by Stepanoff and others,^{14,30–33} Figure 28 shows the results of cavitation tests on two liquids for constant capacity and constant pump speed. No head loss due to cavitation is present at point *C* or at $h_{sv} > h_{suc}$. With cold deaerated water, lowering h_{sv} slightly below h_{suc} produces limited cavitation and a decrease in pump head ΔH to point *C*₁, but Δh_{suc} usually is negligible. With hot water ($T \geq 100^\circ\text{F} = 37.8^\circ\text{C}$) or with many liquid hydrocarbons, a much larger decrease in h_{sv} will be required to produce the same drop in head ΔH that was shown by the cold water test. The *NPSH reduction*, or *NPSH adjustment*, is $\Delta h_{sv} \approx \Delta h_{suc}$. In practice, ΔH has been limited to $\Delta h \leq 0.03H$, for which there is a negligible sacrifice in performance. The pumps usually are made of stainless steel or other cavitation-resistant materials, and the lower *NPSH* results in lower collapse pressure of the vapor bubbles, reducing the damage potential.

Chart for NPSH Reductions A composite chart of *NPSH reductions* for deaerated hot water and certain gas-free liquid hydrocarbons is shown in Figure 29. The curves of vapor pressure versus temperature and the curves of constant *NPSH* reduction were based on laboratory tests with the liquids shown and should be used subject to the following limitations:

1. No *NPSH* reduction should exceed 50% of the *NPSH* required by the pump for cold water or 10 ft (3.0 m), whichever is smaller.
2. *NPSH* may have to be increased *above* the normal cold-water value to avoid unsatisfactory operation when (a) *entrained* air or other noncondensable gas is present in the liquid or (b) *dissolved* air or other noncondensable gas is present in the liquid and the absolute suction pressure is low enough to permit release of the gas from solution.
3. The vapor pressure of hydrocarbon mixtures vary significantly with temperature and so should be determined at pumping temperature (see Reference 27).
4. If the suction system may be susceptible to transient changes in absolute pressure or temperature, a suitable margin of safety in *NPSH* should be provided. This is particularly important with hot water and may exceed the reduction that would otherwise apply with steady-state conditions.
5. Although experience has indicated the reliability of Figure 29 for hot water and the liquid hydrocarbons shown, its use with other liquids is not recommended unless it is clearly understood that the results must be accepted on an experimental basis.

FIGURE 29 *NPSH* reductions for pumps handling liquid hydrocarbons and hot water. This chart has been constructed from test data obtained by using the liquids shown. For applicability to other liquids, refer to the text ($\text{ft} \times 0.3048 = \text{m}$; $\text{lb/in}^2 \times 6.895 = \text{kPa}$). (Hydraulic Institute ANSI/HI 2000 Edition Pump Standards, Reference 27)

USE OF FIGURE 29 Given a fluid having a vapor pressure of 30 lb/in^2 (210 kPa) abs at 100°F (37.8°C). Follow the arrows on the key shown on the chart and obtain an *NPSH* reduction of about 2.3 ft (0.70 m). Since this does not correspond to one of the liquids for which vapor pressure curves are shown on the chart, the use of this *NPSH* reduction should be considered a tentative value only. Given a pump requiring 16-ft (4.9-m) cold-water *NPSH* at the operating capacity, the pump is to handle propane at 55°F (12.8°C). Figure 29 shows the vapor pressure to be about 105 lb/in^2 (733 kPa) abs and the *NPSH* reduction to be about 9.5 ft (2.9 m). Since this exceeds 8 ft (2.44 m), which is half the cold-water *NPSH*, the recommended *NPSH* for the pump handling propane is half the cold-water *NPSH*, or 8 ft (2.44 m). If the temperature of the propane in the previous example is reduced to 14°F (-10°C), Figure 29 shows the vapor pressure to be 50 lb/in^2 (349 kPa) abs and the *NPSH* reduction to be about 5.7 ft (1.74 m), which is less than half the coldwater *NPSH*. The *NPSH* required for pumping propane at 14°F (-10°C) is then $16 - 5.7 = 10.3 \approx 10 \text{ ft}$ ($4.87 - 1.74 = 3.13 \approx 3 \text{ m}$).

Reduction of Cavitation Damage After the pump has been built and installed*, there is little that can be done to reduce cavitation damage. As previously mentioned, sharpening the leading edges of the blades by filing may be beneficial. Stepanoff⁷² has suggested cutting back part of the blades in the impeller eye together with sharpening the tips, for low-specific-speed pumps, as a means of reducing the inlet velocity c_1 and thus lowering σ . Although a small amount of prerotation or prewhirl in the direction of impeller rota-

*Sometimes it is possible to lower the pump, and this should be considered before other alterations are made.

tion may be desirable³⁴, excessive amounts should be avoided. This may require straightening vanes ahead of the impeller and rearranging the suction piping to avoid changes in direction or other obstructions. The cavitation damage to the impeller shown in Figure 20 was believed to have been at least partly due to bad flow conditions produced by two 90° elbows in the suction piping. The planes of the elbows were at 90° to each other, and this arrangement should be avoided.

Straightening vanes in the impeller inlet may increase the *NPSH* requirement at all flow rates. Three or four radial ribs equally spaced around the inlet and extending inward about one-quarter of the inlet diameter are effective against excessive prerotation and may require less *NPSH* than full-length vanes. This is very important with axial-flow pumps, which are apt to have unfavorable cavitation characteristics at partial flow rates. Operation near the best efficiency point usually minimizes cavitation.

The admission of a small amount of air into the pump suction tends to reduce cavitation noise.⁷ This rarely is done, however, because it is difficult to inject the right amount of air under varying head and flow rate conditions and frequently there are objections to mixing air with the liquid pumped.

If a new impeller is required because of cavitation, the design should take into account the most recent advances described in the literature. Gongwer³⁵ has suggested (1) the use of ample fillets where the vanes join the shrouds, (2) sharpened leading edges of vanes, (3) reduction of β , in the immediate vicinity of the shrouds, and (4) raking the leading edges of the vanes forward out of the eye. Increasing the number of vanes for propeller pumps lowers σ for a given submergence. A change in the impeller material may be very beneficial, as described below.

Resistance of Materials to Cavitation Damage Table 8 shows the relative resistance of several metals to cavitation pitting produced by magnetostriction vibration. It will be seen that cast iron, the most commonly used material for impellers, has relatively little pitting resistance relative to bronze and stainless steel, which are readily cast and finished.

Damage due to cavitation erosion is commonly assessed in terms of the depth of penetration. The life of an impeller is generally considered to be the time required for cavitation erosion to reach a depth of 75% of the blade thickness at any point³⁶. The life of any material in years can be expressed as the product of the mean depth of penetration rate

TABLE 8 Cavitation erosion resistance of metals

| Alloy | Magnetostriction weight loss after 2 h, mg |
|---|--|
| Rolled stellite ^a | 0.6 |
| Welded aluminum bronze | 3.2 |
| Cast aluminum bronze | 5.8 |
| Welded stainless steel (2 layers, 17 Cr-7 Ni) | 6.0 |
| Hot rolled stainless steel (26 Cr-13 Ni) | 8.0 |
| Tempered rolled stainless steel (12 Cr) | 9.0 |
| Cast stainless steel (18 Cr-8 Ni) | 13.0 |
| Cast stainless steel (12 Cr) | 20.0 |
| Cast manganese bronze | 80.0 |
| Welded mild steel | 97.0 |
| Plate steel | 98.0 |
| Cast steel | 105.0 |
| Aluminum | 124.0 |
| Brass | 156.0 |
| Cast iron | 224.0 |

^aDespite the high resistance of this material to cavitation damage, it is not suitable for ordinary use because of its comparatively high cost and the difficulty encountered in machining and grinding.

Source: Reference 69.

(*MDPR*, in mm per year) times the thickness of the material in mm. Values of *MDPR* have been deduced³⁷ from the weight loss of test samples of known diameter in a magnetostriction test (Table 8)³⁸. Unfortunately, *MDPR*-values obtained in such tests are not the same as those of actual pumps, as the mode of cavitation varies with pump operating conditions and is generally different from the laboratory results. Nevertheless, laboratory results for *MDPR* have been used to rank the ability of various materials to resist cavitation erosion in pumps. See Section 5.1 for material selection guidelines.

Cavitation-resistant coatings, either metallic or nonmetallic, have found some niche applications. Elastomeric coatings are resilient and resist cavitation through a different erosion mechanism than that of metal. As such, they can be very effective⁶⁹. At least two considerations are involved in the use of coatings for resisting cavitation damage: 1) even if a contemplated coating demonstrates a reduced damage or erosion rate, this reduction must be enough to justify the cost of establishing a satisfactory bond between the coating and the base metal; 2) erosion of both the coating and the base material must be considered in determining the life according to the above 75%-depth criterion. Therefore, the life in this case would be equal to the *MDPR* of the coating times the coating thickness plus the *MDPR* of the base material times the allowable erosion depth of that material.

Inducers It is sometimes difficult or impossible to provide the required *NPSH* for an otherwise acceptable pump. Besides normal industrial situations that might produce a very low available *NPSH*, the need to keep the weight down in aircraft and rocket liquid-propellant pumps has led to high rotative speeds, which, for typical values of *NPSH*, produce extremely high suction specific speeds. The performance-*NPSH* required by the impeller under these circumstances can be provided by a small, axial-flow booster pump, called an inducer, placed ahead of the first-stage impeller³⁹. Inducers are designed to operate with very low *NPSH* and to provide enough head to satisfy the *NPSH* required by the impeller. In fact, long stable cavities are established on the suction sides of the long, lightly-loaded blades of an inducer, which enable it to operate at about twice the suction specific speed of a conventional impeller^{40,41}. At lower than normal flow rates, however, inducers readily produce swirling, destabilizing backflow at the inlet, which can cause excessive pump vibration in high-head pumps. These instabilities can be overcome by various passive design features, such as that described in Reference 39.

The inducers described in Reference 42 (Figure 30) have “constant lead” helical blades. They contribute not more than 5% of the total pump head. Although the efficiency of the inducer alone is low, the reduction in overall pump efficiency is not significant. Because this type of inducer causes prerotation, a careful match between inducer and suction impeller is required. In vertical multistage pumps, where a long shaft can be better supported, a vaned diffuser may be inserted between the inducer and the first-stage impeller. Such an arrangement is very beneficial for operation at reduced flow rate. Reference 42 shows that a suitable inducer-impeller combination can operate at about 50% of the *NPSH* required for the impeller alone at flow rates not exceeding the normal value. The *NPSH* requirement increases rapidly for flow rates above normal. Unless a variable-lead inducer is used^{32,39}, operation in this range should be avoided.

Entrained Air Air or other gases may enter the impeller inlet from several sources. The immediate effect usually will be a drop in pump pressure rise, flow rate, and power. This will be followed by loss of prime if more gas is present than the impeller can handle. A typical limit for commercial industrial pumps is an inlet gas-to-liquid volume fraction (GVF) of 0.03, although specialty pumps such as those used in aircraft (Section 9.19) can handle higher GVF. See also Reference 9, Section 2.1. Air may be released from solution or enter through leaks in the suction piping. Stuffing box air leakage may be prevented by lantern rings supplied with liquid from the pump discharge. If the pump takes water from a sump with a free surface, a vortex may form from the free surface to the impeller inlet. The remedy may be the introduction of one or more baffle plates or even major changes in the sump. For information on proper sump design and the prevention of air-entraining vortices, see Sections 10.1 and 10.2, pp. 457 and 460 of Reference 7, and Reference 43. It is sometimes permissible to inject a small amount of air into the pump

FIGURE 30 Pump fitted with inducer (Reference 42)

suction to reduce the noise and damage from cavitation caused by inadequate *NPSH* or recirculation in the impeller (see Subsection 2.3.2).

STARTING CENTRIFUGAL PUMPS

Priming Centrifugal pumps usually are completely filled with the liquid to be pumped *before starting*. When so filled with liquid, the pump is said to be *primed*. Pumps have been developed to start with air in the casing and then be primed.⁴⁴ This procedure is unusual with low-specific-speed pumps but is sometimes done with propeller pumps¹². In many installations, the pump is at a lower elevation than the supply and remains primed at all times. This is customary for pumps of high specific speed and all pumps requiring a positive suction head to avoid cavitation.

Pumps operated with a suction lift may be primed in any of several ways. A relatively inexpensive method is to install a special type of check valve, called a *foot valve*, on the inlet end of the suction pipe and prime the pump by filling the system with liquid from any available source. Foot valves cause undesirable frictional loss and may leak enough to require priming before each starting of the pump. A better method is to close a valve in the discharge line and prime by evacuating air from the highest point of the pump casing. Many types of vacuum pumps are available for this service. A priming chamber is a tank that holds enough liquid to keep the pump submerged until pumping action can be initiated. Self-priming pumps usually incorporate some form of priming chamber in the pump casing. Section 2.4 and Reference 7 may be consulted for further details.

Torque Characteristics of Drivers Centrifugal pumps of all specific speeds usually have such low starting torques (turning moments) that an analysis of the starting phase of operation seldom is required. Steam and gas turbines have high starting torques, so no special starting procedures are necessary when they are used to drive pumps. If a pump is directly connected to an internal combustion engine, the starting motor of the engine should be made adequate to start both driver and pump. If the starter does not have enough torque to handle both units, a clutch must be provided to uncouple the pump until the driver is started.

Electric motors are the most commonly used drivers for centrifugal pumps. Direct current motors and alternating current induction motors usually have ample starting torque for all pump installations, provided the power supply is adequate. Many types of reduced voltage starters are available⁷ to limit the inrush current to safe values for a given power supply. Synchronous motors are often used with large pumps because of their favorable power-factor properties. They are started as induction motors and run as such up to about 95% of synchronous speed. At this point, dc field excitation is applied and the maximum torque the motor can then develop is called the pull-in *torque*, which must be enough to accelerate the motor and connected inertia load to synchronous speed in about 0.2 s if synchronous operation is to be achieved. Centrifugal pumps usually require maximum torque at the normal operating point, and this should be considered in selecting a driver, particularly a synchronous motor, to be sure that the available pull-in torque will bring the unit to synchronous speed.

Torque Requirements of Pumps The *torque*, or turning moment, for a pump may be estimated from the power curve in USCS units by

$$M = \frac{5252P}{n} \quad (25)$$

and in SI units by

$$M = \frac{9549P}{n}$$

where M = pump torque, lb · ft (N · m)

P = power, hp (kW)

n = speed, rpm

Equation 25 makes no allowance for accelerating the rotating elements or the liquid in the pump. If a 10% allowance for accelerating torque is included, the constant should be correspondingly increased. The time Δt required to change the pump speed by an amount $\Delta n = n_2 - n_1$ is given by

$$\Delta t = \frac{I \Delta n}{k(M_m - M)} \quad (26)$$

where Δt = time, s

I = moment of inertia (flywheel effect) of all rotating elements of driver, pump, and liquid, lb · ft (kg · m²)

Δn = change in speed, rpm

k = 307 in USCS (9.549 in SI)

M_m = driver torque, lb · ft (N · m)

M = pump torque, lb · ft (N · m) (Eq. 25)

The inertia I of the driver and pump usually can be obtained from the manufacturers of the equipment. The largest permissible Δn for accurate calculation will depend on how rapidly M_m and M vary with speed. The quantity $M_m - M$ should be nearly constant over the interval Δn if an accurate estimate of Δt is to be obtained. Torque-speed characteristics of electric motors may be obtained from the manufacturers.

Horizontal-shaft pumps fitted with plain bearings and packed glands require a *break-away torque* of about 15% of M_n , the torque at the normal operating point, to overcome the static friction. This may be reduced to about 10% of M_n if the pump is fitted with antifriction bearings. The breakaway torque may be assumed to decrease linearly with speed to nearly zero when the speed reaches 15 to 20% of normal. Construction of torque-speed curves requires a knowledge of the pump characteristics at normal speed as well as details of the entire pumping system. Some typical examples taken from Reference 7 are given

below. The following forms of the affinity laws (Eqs. 12) are useful in constructing the various performance curves:

$$Q_2 = Q_1 \frac{n_2}{n_1} \quad (27)$$

$$H_2 = H_1 \left(\frac{n_2}{n_1} \right)^2 = H_1 \left(\frac{Q_2}{Q_1} \right)^2 \quad (28)$$

$$P_2 = P_1 \left(\frac{n_2}{n_1} \right)^3 \quad (29)$$

$$M_2 = M_1 \left(\frac{n_2}{n_1} \right)^2 \quad (30)$$

where Q = flow rate

n = speed

H = head

P = power

M = torque

in any consistent units of measure. After speeds n_1 and n_2 are chosen, the subscripts 1 and 2 refer to corresponding points on the characteristic curves for these speeds.

Low-Specific-Speed Pumps Figure 31 shows the constant-speed characteristics of a pump having $n_s \approx 1740$ (0.64) at best efficiency. This pump usually would be started with a valve in the discharge line closed. During the starting phase, the pump operates at shut-off with $P_1 = 25.8$ hp (19.2 kW) and $n_1 = 1770$ rpm. Then, by Eq. 25, $M_1 = 76.6$ lb · ft (103.9 $N \cdot m$). These values may be used in Eq. 30 to evaluate starting torques M_2 at as many speeds n_2 as desired and plotted in Figure 32 as curve BCD . Section AB of the starting torque curve is an estimate of the breakaway torque. If the discharge valve is now opened, the speed remains nearly constant but the torque increases as the capacity and power increase. If the normal operating point is $Q = 1400$ gpm (88.3 l/s) and $P_n = 53.2$ hp (39.7 kW), the motor torque will be $M_n = 158$ lb · ft (214 $N \cdot m$) by Eq. 25. The vertical line DE in Figure 32 shows the change in torque produced by opening the discharge valve.

Instead of starting the pump with the discharge valve closed, let the pump be started with a check valve in the discharge line held closed by a static head of 100 ft (30.5 m). The frictional head in the system may be represented by kQ^2 . The value of k may be estimated from the geometry of the system or from a frictional-loss measurement at any convenient flowrate Q , preferably near the normal capacity Q_n . In this example, $Q_n = 1400$ gpm (88.33 l/s) and $k = 14.4/10^6$ (0.00109). The curve labeled system head 1 in Figure 31 was computed from $H = 100 + (14.4/10^6)Q^2$ ft ($H = 30.48 + 0.00109Q^2$ m) and intersects the head curve at $H = 128$ ft (39.01 m) and $Q_n = 1400$ gpm (88.33 l/s). The normal shutoff head is $H_1 = 153$ ft (46.6 m) at $n_1 = 1770$ rpm. By Eq. 28, the pump will develop a shutoff head $H_2 = 100$ ft (30.5 m) at $n_2 = 1430$ rpm. By Eq. 30, the torque at 1430 rpm will be 50 lb · ft (68 $N \cdot m$), corresponding to point C in Figure 32. The portion ABC of the starting torque curve has already been constructed. Trial-and-error methods must be used to obtain the portion ABC of the starting torque curve.

The auxiliary curves in Figure 33 are useful in constructing the CE portion of the starting torque curve. Select a value of n_2 intermediate between 1427 and 1770 rpm, say $n_2 = 1600$ rpm. In Figure 31, read values of Q_1 , H_1 , and P_1 for speed $n_1 = 1770$ rpm. By Eqs. 27 and 28, determine values of Q_2 and H_2 and plot as shown in Figure 31 until an intersection with the system-head 1 curve is obtained that provides Q_{1600} corresponding to $n = 1600$ rpm. By Eq. 29, determine value of P_2 and plot as shown in Figure 31 until an intersection is obtained with the Q_{1600} line which provides P_{1600} corresponding to $n = 1600$ rpm. Eq. 34 is now used to obtain M_{1600} , which is one point on the desired starting torque curve. The process is repeated for various speeds n_2 until the curve CE in Figure 32 can be drawn. The

FIGURE 31 Characteristics of a 6-by-8 double-section pump at 1770 rpm ($\text{ft} \times 0.3048 = \text{m}$; $\text{gpm} \times 0.06309 = \text{l/s}$; $\text{hp} \times 0.7457 = \text{kW}$ $n_s = 1,740$ ($\Omega_s = 0.64$) (Reference 7)

FIGURE 32 Torque characteristics of 6-by-8 pump shown in Figure 31 ($\text{lb} \cdot \text{ft} \times 1.356 = \text{N} \cdot \text{m}$) (Reference 7)

complete starting torque curve for this example is $ABCE$ in Figure 31, with steady-state operation at point E .

Assume that the pump of the preceding examples is installed in a system having zero static head but a long pipeline with friction head given by $H = (65.4/10^6)Q^2$ ft ($H = 0.00500Q^2$ m), as shown in Figure 31 by the curve labeled system head 2. The valve in the discharge line is assumed to open instantaneously when power is first applied to the pump. The procedure described to construct curve CE of the preceding example must now be used together with the system-head 2 curve of Figure 31 to obtain the curve BE of Figure 32. The complete starting torque curve for this example is ABE in Figure 32, with steady-state operation at point E .

The inertia of the fluid in the system was neglected in solving the previous examples. Some of the power must be used to accelerate the liquid, and this may be appreciable in the case of a long pipeline. Low-specific speed pumps, which are used with long pipelines, have

FIGURE 33 Analysis of 6-by-8 pump shown in Figure 41 ($\text{ft} \times 0.3048 = \text{m}$; $\text{gpm} \times 0.06309 = \text{l/s}$; $\text{lb} \cdot \text{ft} \times 1.356 = \text{N} \cdot \text{m}$; $\text{hp} \times 0.7457 = \text{kW}$) (Reference 7)

FIGURE 34 Characteristics of a 16-in (40.6cm) volute pump with mixed-flow impeller with flat power characteristic ($\text{ft} \times 0.3048 = \text{m}$; $\text{gpm} \times 0.06309 = \text{l/s}$; $\text{hp} \times 0.7457 = \text{kW}$). $n_s = 4570$ ($\Omega_s = 1.672$) (Reference 7)

rising power curves with minimum power at shutoff and maximum power at normal flow rate. Experience has shown that the starting torque-speed curves computed by neglecting the inertia of the liquid are conservative, so inertia effects need not be included. The inertia effect of the liquid does slow the starting operation. If the time required to reach any event, such as a particular speed or flow rate, is required, the inertia of the liquid should be considered, but including it greatly increases the difficulty of computation. References 45 through 48 give general methods for handling problems involving liquid transients.

High-specific-speed pumps have falling power flow rate curves with maximum power at shutoff and minimum power at normal flow rate. Neglecting the inertia of the liquid probably will result in too low a value for the computed starting torque for such pumps. If liquid inertia is to be included, consult References 44 to 47 and Section 8.1.

MEDIUM- AND HIGH-SPECIFIC-SPEED PUMPS Figure 34 shows constant-speed characteristics for a medium-specific-speed pump, $n_s = 4570$ (1.672) at best efficiency. The shutoff power

FIGURE 35 Torque characteristics of pump shown in Figure 34 (Reference 7)

FIGURE 36 Characteristics of a 30-in (76.2-cm) discharge propeller pump at 700 rpm ($\text{ft} \times 0.1048 = \text{m}$; $\text{gpm} \times 0.06309 = \text{l/s}$; $\text{hp} \times 0.7457 = \text{kW}$). $n_s = 12,000$ ($\Omega_s = 4.391$) (Reference 7)

is the same as the power at best efficiency, and the starting torque-speed curve is but little affected by the method of starting, as shown by Figure 35.

Figure 36 shows the constant-speed characteristics of a high-specific-speed propeller pump, $n_s \approx 12,000$ (4.391) at best efficiency. Figure 37 shows the starting torque-speed curve when the pump is started against a static head of 14 ft (4.3 m) and a friction head of 1 ft (0.3 m) at $Q_n = 12,500$ gpm (789 l/s). The system was assumed full of water with a closed check valve at the outlet end of the short discharge pipe. The methods of computation for Figures 35 and 37 were the same as for Figure 32.

Sometimes propeller pumps are started with the pump submerged but with the discharge column filled with air. In such a case, the torque-time characteristic for the driver must be known and a step-by-step calculation carried out. If the discharge column is a siphon initially filled with air, the starting torque may exceed the normal running torque during some short period of the starting operation. If the pump is driven by a synchronous

FIGURE 37 Torque characteristics of pump shown in Figure 36 (Reference 7)

motor, it is particularly important to investigate the starting torque in the range of 90 to 100% of normal speed to make sure that the pull-in torque of the motor is not exceeded. For additional information regarding starting high-specific-speed pumps discharging through long and large diameter systems, see Section 8.1.

Miscellaneous Requirements Pumps handling hot liquids should be warmed up to operating temperature before being started unless they have been especially designed for quick starting. Failure to do this may cause serious damage to wearing rings, seals, and any hydraulic balancing device that may be present. A careful check of the installation should be made before starting new pumps, pumps that have had a major overhaul, or pumps that have been standing idle for a long time. It is very important to follow the manufacturer's instructions when starting boiler-feed pumps. If these are unavailable, Reference 7 may be consulted. Ascertain that the shaft is not frozen, that the direction of rotation is correct, preferably with the coupling disengaged, and that bearing lubrication and gland cooling water meet normal requirements. Failure to do this may result in damage to the pump or driver.

A pump may run backwards at runaway speed if the discharge valve fails to close following shutdown. Any attempt to start the pump from this condition will put a prolonged overload on the motor. Figure 38 shows one example of the torque-speed transient for a pump, $n_s = 1700$ (0.622), started from a runaway reversed speed while normal pump head was maintained between the section and discharge flanges. In most practical cases, water hammer effects would make this transient even more unfavorable than Figure 38 indicates. The duration of such a transient will always be much longer than the normal starting time, and so protective devices would probably disconnect the motor from the power supply before normal operation could be achieved. Consult Section 8.1 for additional information on this subject.

REGULATION OF FLOW RATE

Flow rate variation ordinarily is accomplished by a change in pump head, speed, or both simultaneously. The flow rate and power input of pumps with specific speeds up to about 4000 (1.464) double suction increase with decreasing head, so the drivers of such pumps may be overloaded if the head falls below a safe minimum value. Increasing the head of high-specific-speed pumps decreases the flow rate but increases the power input. The drivers of these pumps should either be able to meet possible load increases or be equipped with suitable overload protection. Flow rate regulation by the various methods given below may be manual or automatic (see also References 1, 7, 12, 34 and 49).

FIGURE 38 Torque characteristics of a double-suction pump, $n_s \approx 1700$ (0.64), from reversed runaway speed to normal forward speed (Reference 7)

FIGURE 39 Power requirements of two double-suction pumps in series operated at constant head and variable flow rate. Total $H_n = 382$ ft (116 m) for both pumps at 1800 rpm ($\text{gpm} \times 0.06309 = \text{l/s}$ $\text{hp} \times 0.7457 = \text{kW}$) (Reference 50). Curve AA: constant speed with discharge throttling. Curve BB: synchronous motor with variable-speed hydraulic coupling on each pump. Curve CC: variable-speed wound-rotor induction motor. Curve DD: dc motor with rectifier and shunt field control. Curve EE: synchronous motor with variable-speed constant-efficiency mechanical speed reducer

Discharge Throttling This is the cheapest and most common method of flow rate modulation for low- and medium-specific-speed pumps. Usually its use is restricted to such pumps. Partial closure of any type of valve in the discharge line will increase the system head so the system-head curve will intersect the pump head curve at a smaller flow rate, as shown in Figure 40. Discharge throttling moves the operating point to one of lower efficiency, and power is lost at the throttle valve. This may be important in large installations, where more costly methods of modulation may be economically attractive. Throttling to the point of cutoff may cause excessive heating of the liquid in the pump. This may require a bypass to maintain the necessary minimum flow or use of different method of modulation. This is particularly important with pumps handling hot water or volatile liquids, as previously mentioned. Refer to Section 8.2 for information regarding the sizing of a pump bypass.

Suction Throttling If sufficient *NPSH* is available, some power can be saved by throttling in the suction line. Jet engine fuel pumps frequently are suction throttled⁹ because discharge throttling may cause overheating and vaporization of the liquid. At very low flow rate, the impellers of these pumps are only partly filled with liquid, so the power input and temperature rise are about one-third the values for impellers running full with discharge throttling. The capacity of condensate pumps frequently is submergence-controlled,⁷ which

is equivalent to suction throttling. Special design reduces cavitation damage of these pumps to a negligible amount, the energy level (Section 2.1) being quite low.

Bypass Regulation All or part of the pump flow may be diverted from the discharge line to the pump suction or other suitable point through a bypass line. The bypass may contain one or more metering orifices and suitable control valves. Metered bypasses are commonly used with boiler-feed pumps for reduced-flow operation, mainly to prevent overheating. There is a considerable power saving if excess capacity of propeller pumps is bypassed instead of using discharge throttling.

Speed Regulation This can be used to minimize power requirements and eliminate overheating during flow rate modulation. Steam turbines and internal combustion engines are readily adaptable to speed regulation at small extra cost. A wide variety of variable-speed mechanical, magnetic, and hydraulic drives are available, as well as both ac and dc variable-speed motors. Usually variable-speed motors are so expensive that they can be justified only by an economic study of a particular case. Figure 39 shows a study by Richardson⁵⁰ of power requirements with various drivers wherein substantial economies in power may be obtained from variable-speed drives.

Regulation by Adjustable Vanes Adjustable guide vanes ahead of the impeller have been investigated and found effective with a pump of specific speed $n_s = 5700$ (2.086). The vanes produced a positive prewhirl that reduced the head, flow rate, and efficiency. Relatively little regulation was obtained from the vanes with pumps having $n_s = 3920$ (1.204) and 1060 (0.39). Adjustable outlet diffusion vanes have been used with good success on several large European storage pumps for hydroelectric developments. Propeller pumps with adjustable-pitch blades have been investigated with good success. Wide flow rate variation was obtained at constant head and with relatively little loss in efficiency. These methods are so complicated and expensive that they have very limited application in practice. Reference 34 may be consulted for further discussion and bibliography.

Air Admission Admitting air into the pump suction has been demonstrated as a means of flow-rate regulation, with some savings in power over discharge throttling. Usually air in the pumped liquid is undesirable, and there is always the danger that too much air will cause the pump to lose its prime. The method has rarely been used in practice but might be applicable to isolated cases.

PARALLEL AND SERIES OPERATION

Two or more pumps may be arranged for parallel or series operation to meet a wide range of requirements in the most economical manner. If the pumps are close together, that is, in the same station, the analysis given below should be adequate to secure satisfactory operation. If the pumps are widely separated, as in the case of two or more pumps at widely spaced intervals along a pipeline, serious pressure transients may be generated by improper starting or stopping procedures. The analysis of such cases may be quite complicated, and References 46 to 48 should be consulted for methods of solution.

Parallel Operation Parallel operation of two or more pumps is a common method of meeting variable-flow-rate requirements. By starting only those pumps needed to meet the demand, operation near maximum efficiency can usually be obtained. The head-flow characteristics of the pumps need not be identical, but pumps with unstable characteristics may give trouble unless operation only on the steep portion of the characteristic can be assured. Care should be taken to see that no one pump, when combined with pumps of different characteristics, is forced to operate at flows less than the minimum required to prevent recirculation. See the discussion that follows on operation at other than normal flow rate. Multiple pumps in a station provide spares for emergency service and for the downtime needed for maintenance and repair.

FIGURE 40 Head-flow curves of pumps operating in parallel

The possibility of driving two pumps from a single motor should always be considered, as it usually is possible to drive the smaller pumps at about 40% higher speed than a single pump of twice the capacity. The saving in cost of the higher-speed motor may largely offset the increased cost of two pumps and give additional flexibility of operation.

One of the first steps in planning for multiple-pump operation is to draw the system-head curve, as shown in Figure 40. The system head consists of the static head H_s and the sum H_f of the pipe-friction head and the head lost in the valves and fittings (see Sections 8.1 and 8.2). The head curves of the various pumps are plotted on the same diagram, and their intersections with the system-head curve show possible operating points. *Combined pump head curves* are drawn by adding the flow rates of the various combinations of pumps for as many values of the head as necessary. The intersection of any combined H - Q curve with the system-head curve is an operating point. Figure 40 shows two pump head curves and the combined curve. Points 1, 2, and 3 are possible operating conditions. Additional operating points may be obtained by changing the speed of the pumps or by increasing the system-head loss by throttling. Any number of pumps in parallel may be included on a single diagram, although separate diagrams for different combinations of pumps may be preferable.

The overall efficiency η of pumps in parallel is given by

$$\eta = \frac{H(\text{sp. gr.})}{k} \times \frac{\sum Q}{\sum P} \quad (31)$$

where H = head, ft (m)

sp. gr. = specific gravity of the liquid

k = 3960 USCS (0.1021 SI)

$\sum Q$ = sum of the pump flow rates, gpm (l/s)

$\sum P$ = total power supplied to all pumps, hp (W)

Series Operation Pumps are frequently operated in series to supply heads greater than those of the individual pumps. The planning procedure is similar to the case of pumps in parallel. The system-head curve and the individual head-flow curves for the pumps are plotted as shown in Figure 41. The pump heads are added as shown to obtain the combined pump head curve. In this example, Pump 2 operating alone will deliver no liquid because its shutoff head is less than the system static head.

There are two possible operating points, 1 and 2, as shown by the appropriate intersections with the system-head curve. As with parallel operation, other operating points

FIGURE 41 Head-flow curves of pumps operating in series

could be obtained by throttling or by changing the pump speeds. The overall efficiency of pumps in series is given by

$$\eta = \frac{Q(\text{sp. gr.})}{k} \times \frac{\sum H}{\sum P} \quad (32)$$

wherein the symbols are the same as for parallel operation. It is important to note that the stuffing box pressure of the second pump is increased by the discharge pressure of the first pump. This may require a special packing box for the second pump with leakoff to the suction of the first pump. The higher suction pressure may increase both the first cost and the maintenance costs of the second pump.

OPERATION AT OTHER THAN THE NORMAL FLOW RATE

Centrifugal pumps usually are designed to operate near the point of best efficiency, but many applications require operation over a wide range of flow rates, including shutoff, for extended periods of time. Pumps for such service are available but may require special design and construction at higher cost. Noise, vibration, and cavitation may be encountered at low flow rates. Large radial shaft forces at shutoff as well as lack of through flow to provide cooling may cause damage or breakage to such parts as shafts, bearings, seals, glands, and wearing rings of pumps not intended for such service. Some of the phenomena associated with operation at other than normal flow rate are described below.

Recirculation There is a small flow from impeller discharge to suction through the wearing rings and any hydraulic balancing device present. This takes place at all flow rates, but does not usually contribute to raising the liquid temperature very much unless operation is near shutoff.

When the flow rate has been reduced by throttling (or as a result of an increase in system head), a secondary flow called *recirculation* begins. Recirculation is a flow reversal due to separation at the suction and at the discharge tips of the impeller vanes. All impellers

FIGURE 42 Suction recirculation

FIGURE 43 Discharge recirculation

have a critical flow rate at which recirculation occurs. The flow rates at which suction and discharge recirculation begin can be controlled to some extent by design, but recirculation cannot be eliminated (see Figure 6 in Section 2.1).

Suction recirculation is the reversal of flow at the impeller eye. A portion of the flow is directed out of the eye at the eye diameter, as shown in Figure 42, and travels upstream with a rotational velocity approaching the peripheral velocity of the diameter. A rotating annulus of liquid is produced upstream from the impeller inlet, and through the core of this annulus passes an axial flow corresponding to the output flow rate of the pump. In pumps equipped with long, straight suction nozzles but no suction elbow, this rotating fluid has been detected over considerable distances upstream from the impeller eye. Suction pressures measured at wall taps where this phenomenon is present are always higher than the true average static pressure across the measuring section. This means that the pump head as determined from wall taps is less than it would be if true average static pressures were measured. The high shear rate between the rotating annulus and the axial flow through the core produces vortices that form and collapse, producing noise and cavitation in the suction of the pump.

Discharge recirculation is the reversal of flow at the discharge tips of the impeller blades, as shown in Figure 43. The high shear rate between the inward and outward relative velocities produces vortices that cavitate and can attack the pressure side of the blades. This phenomenon, which tends to occur at a lower flow rate than the highest Q for suction recirculation, also involves stalled flow from the diffuser vanes or volute tongue(s). Separated reversed flow recirculates and emerges from these vane systems back into the impeller with negative swirl (that is, swirl opposite to the direction of rotation). The impeller must expend significant power to redirect the portion of this fluid (that reenters it) out again—with positive swirl. As discussed in Section 2.1, the portion of this backflow from the diffuser or volute that enters the spaces outside the impeller shrouds and adjacent to the casing walls has the potential to reverse the axial thrust of the impeller, and this reversal can fluctuate if the backflow is unsteady (as separated, recirculating flow normally is) and not always feeding the same side of the impeller.

The flow rate Q_{sr} below which suction recirculation occurs is directly related to the design suction-specific speed S of the pump. The higher the suction-specific speed, the closer will be the beginning of recirculation to the flow rate at best efficiency. Figure 44 shows the relation between the suction specific speed and suction recirculation for pumps

FIGURE 44 Influence of the design value of suction specific speed S on the flow rate Q_{SR} below which suction recirculation occurs. $500 < n_s < 2500$; $(0.18 < \Omega_s < 0.91)$ for single-suction or one side of a double-suction impeller. The ordinate is Q_{SR}/Q_{BEP} in percent. (To obtain Ω_{ss} , divide S by 2733.)

FIGURE 45 Influence of the design value of suction specific speed S on the flow rate Q_{SR} below which suction recirculation occurs. $2500 < n_s < 10,000$; $(0.91 < \Omega_s < 3.66)$ for single-suction or one side of a double-suction impeller. The ordinate is Q_{SR}/Q_{BEP} in percent. (To obtain Ω_{ss} , divide S by 2733.)

up to 2500 (0.915) specific speed, and Figure 45 shows the same relation for pumps up to 10,000 (3.659) specific speed.

Despite the existence of suction and discharge recirculation, the mechanical response of the pump will not be serious unless the energy level is high. In other words, most pumps can indeed be operated at $Q < Q_{SR}$. The minimum flow rate or simply “minimum flow” Q_{min} is quantified in Section 2.1. As energy level is increased, Q_{min} approaches Q_{SR} in the limit. Examples of the difference between Q_{min} and Q_{SR} are as follows: For water pumps rated at 2500 gpm (158 l/s) and 150 ft (45.7 m) total head or less, the minimum operating flows can

be as low as 50% of the suction recirculation values shown for continuous operation and as low as 25% for intermittent operation. For hydrocarbons, the minimum operating flows can be as low as 60% of the suction recirculation values shown for continuous operation and as low as 25% for intermittent operation.^{51, 52, 53}

Temperature Rise Under steady-state conditions, friction and the work of compression increase the temperature of the liquid as it flows from suction to discharge. A further temperature increase may arise from liquid returned to the pump suction through wearing rings, a balancing device, or a minimum-flow bypass line that protects the pump when operating at or near shutoff.

Assuming that all heat generated remains in the liquid, the temperature rise is

$$\Delta T = \frac{gH \times (1 - \eta)}{g_o C_p \eta J} + \Delta T_c \quad (33)$$

where $g/g_o = 1$ lbf/lbm; but when using SI units, g/g_o is replaced by $9.80665 \text{ m/s}^2 (= g \text{ in the SI system})$. ΔT_c is due to the compression of the liquid and is not a consequence of loss or dissipation as is the term involving the pump efficiency η (see Section 2.1). As shown in Reference 1 of Section 2.1, ΔT_c is 3°F per 1000 psi (0.24°C per MPa) of pump pressure rise for hydrocarbon fuels. For boiler feedwater at 350°F (177°C), $\Delta T_c = 1.6^\circ\text{F}$ per 1000 psi (0.129°C per MPa), but it is much smaller for cold water. By consulting tables of properties for the liquid phase of the fluid being pumped and assuming the compression process between the actual inlet and discharge pressures to be isentropic, ΔT_c can be determined. This is important if Eq. 33 is used to evaluate overall pump efficiency from temperature rise measurements. ΔT and ΔT_c are often of the same order of magnitude at BEP, and serious errors have been made by excluding ΔT_c from the efficiency computation. At very low, off-BEP flow rates, ΔT will be high in comparison to ΔT_c ; so, the latter can be safely ignored in temperature rise calculations at such low-efficiency conditions.

In practice, determination of efficiency from ΔT -measurements is accomplished by the direct thermodynamic method⁵⁴, rather than by the ΔT_c -method. Both approaches are based on the definition of pump efficiency as the ratio of an isentropic rise of total enthalpy ($= g\Delta H$) to the actual rise of total enthalpy (Eq. 1 of Section 2.1), allowances being made for the usually small external power losses that do not appear in the pumped fluid (such as bearing drag) and the similarly small effects of heat transferred between pump and surroundings. In the direct thermodynamic method, the enthalpy rise Δh is found from the chain rule,

$$\Delta h = \int dh = \int [(\partial h / \partial p)_T dp + (\partial h / \partial T)_p dT] = a \Delta p + C_p J \Delta T$$

the coefficients a and $C_p J$ being average values of the two partial derivatives as found from tables of thermodynamic properties of the fluid. Values of these partial derivatives are conveniently tabulated for water in Reference 54.

General service pumps handling cold liquids may be able to stand a temperature rise as great as 100°F (56°C). Most modern boiler-feed pumps may safely withstand a temperature rise of 50°F (28°C). The NPSH required to avoid cavitation or to prevent flashing of hot liquid returned to the pump suction may be the controlling factor. Minimum flow may be dictated by other factors, such as recirculation and unbalanced radial and axial forces on the impeller. Axial forces can be the controlling factor with single-stage double-suction pumps.

It is especially important to protect even small pumps handling hot liquids from operation at shutoff. This is usually done by providing a bypass line fitted with a metering orifice to maintain the minimum required flow through the pump. In the case of boiler-feed pumps, the bypass flow usually is returned to one of the feed-water the water heaters. Unless especially designed for cold starting, pumps handling hot liquids should be warmed up gradually before being put into operation.

Radial Thrust Ideally, the circumferential pressure distribution at the impeller exit is uniform at the design condition (as explained in Section 2.1); however, it becomes non-

uniform at off-BEP flow rates. An exception is that concentric collecting configurations will produce non-uniform pressure distributions at the BEP. Any non-uniformity leads to a radial force on the pump shaft called the radial thrust or radial reaction. The radial thrust F_r in pounds (newtons) is

$$F_r = kK_r(\text{sp. gr.})HD_2b_2 \quad (34)$$

where $k = 0.433$ USGS (9790 SI)

K_r = experimentally determined coefficient

sp. gr. = specific gravity of the liquid pumped (equal to unity for cold water)

H = pump head, ft (m)

D_2 = outside diameter of impeller, in (m)

b_2 = breadth of impeller at discharge, including shrouds, in (m)

Values of K_r , determined by Agostinelli et al.⁵⁵ for single-volute pumps are given in Figure 46 as functions of specific speed and flow rate. The magnitude and direction of F_r on the pump shaft may be estimated from Figure 47, but Eq. 34 probably will be more accurate for determining the magnitude of the force. The radial thrust usually is minimum near $Q = Q_n$, the flow rate at best efficiency, but rarely goes completely to zero. Near shutoff, F_r usually is maximum and may be a considerable force on the shaft in high-head pumps.

The radial thrust can be made much smaller throughout the entire flow-rate range by using a double volute (twin volute) or a concentric casing. These designs should be considered, particularly if the pump must operate at small flow rates. Figures 48 to 50 compare radial forces generated by three types of casings: a standard volute, a double volute, and a modified concentric casing. The latter casing was concentric with the impeller for 270° from the tongue and then enlarged in the manner of a single volute to form the discharge nozzle. The magnitude and direction of F_r on the pump shaft for the modified concentric casing may be estimated from Figure 51. The direction of F_r on the pump shaft with a double volute was somewhat random but in the general vicinity of the casing tongue. Radial forces on pumps fitted with diffuser vanes usually are rather small, although they may be significant near shutoff due to stall in some of the passages and not in others.

EXAMPLE Consider a single-stage centrifugal pump, $n_s = 2000$ (0.732) at best efficiency, handling cold water, sp. gr. = 1.0. Estimate the radial thrust on the impeller at half the normal flow rate when fitted with (a) a single volute, (b) a modified concentric casing, and (c) a double volute. Impeller dimensions are $D_2 = 15.125$ in (38.4 cm) and $b_2 = 2.5$ in (6.35 cm). The shutoff head is $H = 252$ ft (76.8 m), and the head at half capacity is $H = 244$ ft (74.4 m).

FIGURE 48 Comparison of the effect of three casing designs on radial forces for $n_s = 1165$ (0.426) (Reference 55)

FIGURE 49 Comparison of the effect of three casing designs on radial forces for $n_s = 2120$ (0.776) (Reference 55)

FIGURE 50 Comparison of effect of three casing designs on radial forces for $n_s = 3500$ (1.281) (Reference 55)

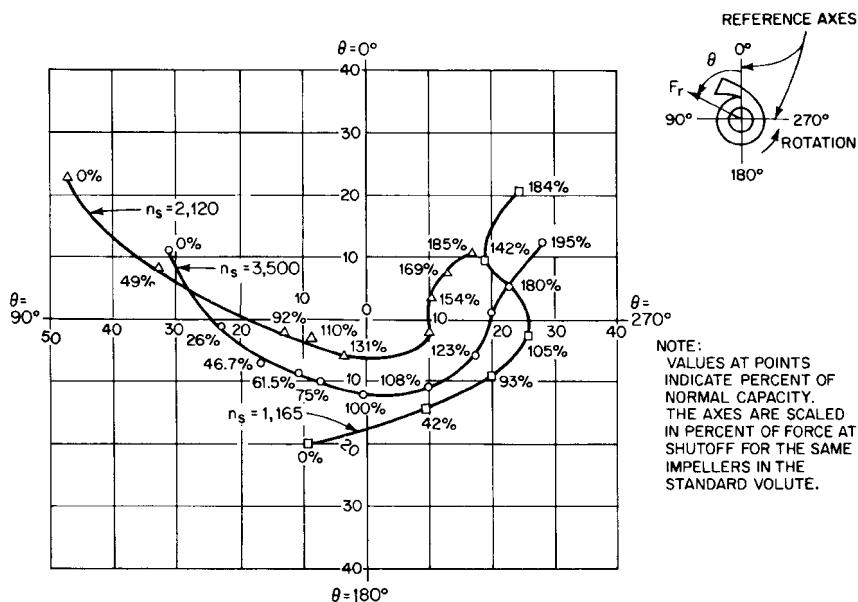

FIGURE 51 Polar plot showing direction of resultant radial forces for modified concentric casings at various flow rates and specific speeds; namely, 1,165 (0.426), 2,120 (0.776), and 3500 (1.281). The casings were concentric for 270° from the tongue. (Reference 55)

Solution

(a) $K_r = 0.2$ from Figure 46, by Eq. 34.

$$F_r = (0.433)(0.2)(1.0)(244)(15.125)(2.5) = 799 \text{ lb (3554 N)}$$

Estimating between the curves for $n_s = 2370$ (0.867) and 1735 (0.635) in Figure 47, the direction of F_r on the shaft should be about 65° to 70° from the casing tongue in the direction of rotation.

(b) Use Figure 49, $n_s = 2120$ (0.776), which is nearest to $n_s = 2000$ (0.730), to find the radial force for a modified concentric casing at half flow, which is about 33%

of shutoff value for a single-volute casing. From Figure 46, for a single-volute casing at shutoff, $K_r = 0.34$ and

$$F_r = (0.433)(0.34)(1.0)(252)(15.125)(2.5) = 1403 \text{ lb (6241 N)}$$

Then, for a modified concentric casing at half flow,

$$F_r = (0.33)(1403) = 463 \text{ lb (2059 N)}$$

From Figure 51, the direction of F_r should be about 75° to 80° from the casing tongue in the direction of rotation.

- (c) From Figure 49, the radial force for a double-volute casing is about 8% of the shutoff value for the single-volute casing, and so

$$F_r = (0.08)(1403) = 112 \text{ lb (499 N)}$$

According to Agostinelli et al.,⁵⁵ the direction of the radial thrust in double-volute casings was found to be generally toward the casing tongue. Stepanoff¹² has found this direction to follow approximately that in single-volute casings (see also Biheller⁵⁶).

Axial Thrust See Section 2.1 and 2.2.1.

ABNORMAL OPERATION

Complete Pump Characteristics Many types of abnormal operation involve reversed pump rotation, reversed flow direction, or both, and special tests are required to cover these modes of operation. Several methods of organizing the data have been proposed, and each has certain advantages. The Thoma diagrams shown in Figures 52 and 53⁴⁵ are easily understood and are truly *complete characteristics diagrams* because all possible modes of operation are covered (see also Reference 57).

Figure 54 shows schematic cross-sections of the two pumps tested by Swanson⁵⁸ for which characteristics are given in Figure 53.

The *Karman circle diagram* (Reference 59) attempted to show the complete characteristics as a four-quadrant contour plot of surfaces representing head and torque with speed and flow rate as base coordinates. Because the head and torque tend to infinity in two zones of operation, another diagram would be required to show the complete pump characteristics. The data presented in such a diagram are, nevertheless, adequate for almost all requirements. One example of a circle diagram is given in Figures 55 and 56. Other examples may be found in References 12, 58, and 59.

Frequently, tests with negative head and torque have been omitted so that only half of the usual circle diagram could be shown. This has been called a *three-quadrant plot*, but the information necessary to predict an event, such as possible water-column separation following a power failure, is lacking.

Power Failure Transient A sudden power failure that leaves a pump and driver running free may cause serious damage to the system. Except for rare cases where a flywheel is provided, the pump and driver usually have a rather small moment of inertia, and so the pump will slow down rapidly. Unless the pipeline is very short, the inertia of the liquid will maintain a strong forward flow while the decelerating pump acts as a throttle valve. The pressure in the discharge line falls rapidly and, under some circumstances, may go below atmospheric pressure, both at the pump discharge and at any points of high elevation along the pipeline. The minimum pressure head which occurs during this phase of the motion is called the *downsurge*, and it may be low enough to cause vaporization followed by complete separation of the liquid column. Pipelines have collapsed under the external atmospheric pressure during separation. When the liquid columns rejoin, following separation, the shock pressures may be sufficient to rupture the pipe or the pump

FIGURE 52 Complete pump characteristics. Specific speeds: Voith pump $n_s = 1,935$ (0.708); Delaval pump $n_s = 1,500$ (0.549). (Reference 45)

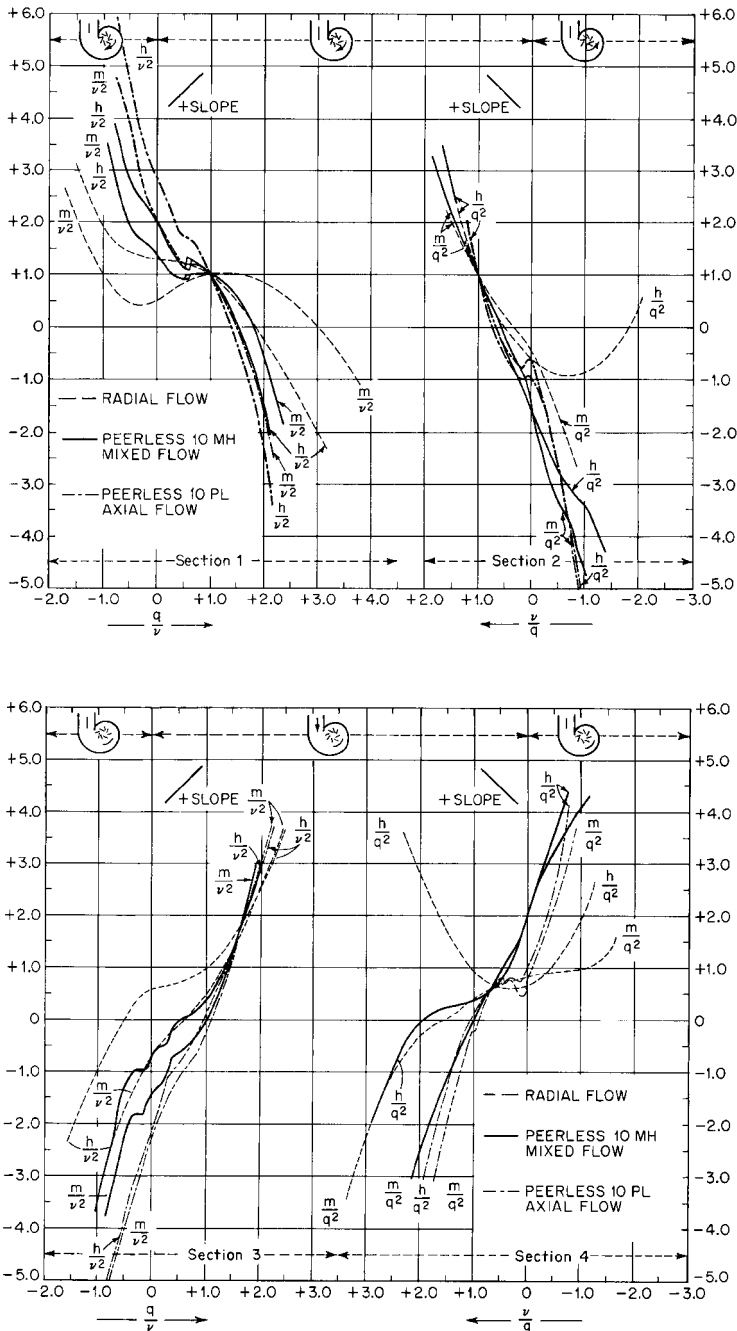

FIGURE 53 Complete pump characteristics. Specific speeds: Radial flow - $n_s = 1800$ (0.659); Peerless 10MH mixed flow - $n_s = 7,550$ (2.763); Peerless 10PL axial flow - $n_s = 13,500$ (4.940). (Reference 45)

FIGURE 54 Schematic cross sections of high-specific-speed pumps. $n_s = 13,500$ (4,940) for axial flow pump; $n_s = 7,550$ (2,763) (Reference 45)

casing. Closing a valve in the discharge line will only worsen the situation, and so valves having programmed operation should be closed very little, if at all, before reverse flow begins.

Reversed flow may be controlled by valves or by arranging to have the discharge pipe empty while air is admitted at or near the outlet. If reversed flow is not checked, it will bring the pump to rest and then accelerate it with reversed rotation. Eventually the pump will run as a turbine at the runaway speed corresponding to the available static head diminished by the frictional losses in the system. However, while reversed flow is being established, the reversed speed may reach a value considerably in excess of the steady-state runaway speed. Maximum reversed speed appears to increase with increasing efficiency and increasing specific speed of the pump. Calculations indicate maximum reversed speeds more than 150% of normal speed for $n_s = 1935$ (0.708) and $\eta = 84.1\%$ ⁴⁵. This should be considered in selecting a driver, particularly if it is a large electric motor.

There will be a pressure increase, called the *upsurge*, in the discharge pipe during reversed flow. The maximum upsurge usually occurs a short time before maximum reversed speed is reached and may cause a pressure as much as 60% or more above normal at the pump discharge. A further discussion of power-failure transients is given in Section 8.3.

ANALYSIS OF TRANSIENT OPERATION The data of Figures 52 and 53 have been presented in a form suitable for general application to pumps having approximately the same specific speeds as those tested. The symbols are $h = H/H_n$, $q = Q/Q_n$, $m = M/M_n$, and $\nu = n/n_n$, wherein H , Q , M , and n represent instantaneous values of head, flow rate, torque, and speed respectively and the subscript n refers to the values at best efficiency for normal constant-speed pump operation. Any consistent system of units may be used. According to the affinity laws (Eqs. 12), q is proportional to ν , and h and m are proportional to ν^2 . Thus the affinity laws are incorporated in the scales of the diagrams. Figures 52 and 53 are divided into sections for convenience in reading data from the curves. The curves of sections 1 and 3 extend to infinity as q/ν increases without limit in either the positive or negative direction. This difficulty is eliminated by sections 2 and 4, where the curves are plotted against ν/q , which is zero when q/ν becomes infinite.

Usually any case of transient operation would begin at or near the point $q/\nu = \nu/q = 1$, which appears in both sections 1 and 2 of Figures 52 and 53. The detailed analysis of transient behavior is beyond the scope of this treatise. An analytical solution by the rigid column method, in which the liquid is assumed to be a rigid body, is given in Reference 45. Friction is easily included, and the results are satisfactory for many cases. The same reference includes a semigraphical solution to allow for elastic waves in the liquid, but friction must be neglected. Graphical solutions including both elastic waves and friction are discussed in References 45 to 48. Computer solutions of a variety of transient problems are discussed in Reference 47. These offer considerable flexibility in the analysis once the necessary programs have been prepared.

FIGURE 55 Circle diagram of pump characteristics. Specific speed $n_s = 4200$ (1.537). (Courtesy Combustion Engineering)

Some extreme conditions of abnormal operation can be estimated at points where the curves of Figures 52 and 53 cross the zero axes and are listed in Table 9. The data for Columns 2 to 4 of Table 9 were read from Sections 2 of Figures 52 and 53, and the data for Columns 6 and 7 were read from Sections 3. Column 8 was computed from Column 7 by assuming $h = 1$. Let the pump having $n_s = 1500$ (0.549) deliver cold water with normal head $H_n = 100$ ft (30.48 m), and let the center of the discharge flange be 4 ft (1.2 m) above the free surface in the supply sump. The discharge pressure head following power failure may be estimated by assuming the inertia of the rotating elements to be negligible relative to the inertia of the liquid in the pipeline. Then $q = 1$ and, from Column 2 of Table 9, the downsurge pressure head is $(-0.22)(100) - 4 = -26$ ft (-7.9 m), which is not low enough to cause separation of the water column.

FIGURE 56 Explanatory diagram for Figure 55

TABLE 9 Abnormal operating conditions of several pumps

| Specific speed n_s (Ω_s) | Downsurge | | | | Runaway turbine | | |
|---|-----------------------------|-------|---------------------------|---------|-----------------|---------|---------|
| | Free-running $m/q^2 = 0$ | | Locked-rotor $v/q = 0$ | | $m/v^2 = 0$ | | $h = 1$ |
| | h/q^2 | v/q | h/q^2 | m/q^2 | q/v | h/v^2 | v |
| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| 1500 (0.549) ^a | -0.22 | 0.36 | -0.55 | -0.53 | 0.46 | 0.77 | 1.14 |
| 1800 (0.659) | -0.24 | 0.31 | -0.60 | -0.44 | 0.56 | 0.75 | 1.16 |
| 1935 (0.708) | -0.36 | 0.32 | -0.94 | -0.60 | 0.41 | 0.66 | 1.23 |
| 7550 (2.763) | -0.23 | 0.56 | -1.57 | -1.38 | 0.99 | 0.38 | 1.62 |

^aDouble-suction.

Actually the downsurge would be less than this because of the effects of inertia and friction, which have been neglected. If this pump were stopped suddenly by a shaft seizure or by an obstruction fouling the impeller, Column 4 of Table 9 shows the downsurge to be $(-0.55)(100) - 4 = -59$ feet (-18 m), which would cause water column separation and, probably, subsequent water hammer. If, following power failure, the pump were allowed to operate as a no-load turbine under the full normal pump head, Column 8 of Table 9 shows the runaway speed would be 1.14 times the normal pump speed. The steady-state runaway speed usually would be less than this because the effective head would be decreased by friction, but higher speeds would be reached during the transient preceding steady-state operation. Column 8 shows that runaway speeds increase with increasing specific speed.

FIGURE 57A through C Pump assembly and rotation (Reference 7)

Incorrect Rotation Correct rotation of the driver should be verified before it is coupled to the pump (Figure 57). Sections 3 of Figures 52 and 53 show that reversed rotation might produce some positive head and flow rate with pumps of low specific speed, but at very low efficiency. It is unlikely that positive head would be produced by reversed rotation of a high-specific-speed pump.

Reversed Impeller Some double-suction impellers can be mounted reversed on the shaft. If the impeller is accidentally reversed, as at B in Figure 57, the flow rate and efficiency probably will be much reduced and the power consumption increased. Care should be taken to prevent this, as the error might go undetected in some cases until the driver was damaged by overload. Table 1 shows performance data for six pumps with reversed impellers. At least one of these would overload the driver excessively.

Further discussion of abnormal operating conditions may be found in References 7, 12, and 34.

Vibration Vibration caused by flow through wearing rings and by cavitation has been discussed in the foregoing and some remedies indicated. Vibration due to unbalance is not usually serious in horizontal units but may be of major importance in long vertical units, where the discharge column is supported at only one or two points. The structural vibrations may be quite complicated and involve both natural frequencies and higher harmonics. Vibration problems in vertical units should be anticipated during the design stage. If vibration is encountered in existing units, the following steps may help to reduce it: (1) dynamically balance all rotating elements of both pump and motor; (2) increase the rigidity of the main support and of the connection between the motor and the discharge column; (3) change the stiffness of the discharge column to raise or lower natural frequencies as required. A portable vibration analyzer may be helpful in this undertaking. Kovats⁶⁰ has discussed the analysis of this problem in some detail.

Structural vibrations can occur in most pump types. Typical sources are a) bearing housings—due to the commonly encountered cantilever construction, b) couplings, c) rotor instabilities stemming from excessive ring clearances and consequent loss of Lomakin stiffening of long-shaft multistage pumps, and d) hydraulic unbalance—due to dimensional variations in flow passages and clearances⁶¹.

PREDICTION OF EFFICIENCY FROM MODEL TESTS

Many pumps used in pumped storage power plants and water supply projects are so large and expensive that extensive use is made of small models to determine the best design. It is often necessary to estimate the efficiency of a prototype pump, as a part of the guaran-

tee, from the performance of a geometrically similar model. A model and prototype are said to operate under dynamically similar conditions when

$$Dn/\sqrt{H} = D'n'/\sqrt{H'},$$

where D = impeller diameter

n = pump speed

H = pump head

in any consistent units of measure. Primed quantities refer to the model and unprimed quantities to the prototype. Dynamic similarity is a prerequisite to model-prototype testing so that losses that are proportional to the squares of fluid velocities, called *kinetic losses*, will scale directly with size and not change the efficiency. Surface frictional losses are boundary-layer phenomena which depend on Reynolds number

$$Re = D\sqrt{H}/\nu,$$

where ν = kinematic viscosity of the liquid pumped.

(See also Section 2.1, Eqs. 36–40.) Reynolds numbers increase with increasing size, and, within limits, surface frictional-loss coefficients decrease with increasing Reynolds number. This leads to a gain in efficiency with increasing size. Computational difficulties have forced an empirical approach to the problem. Details of the development of a number of formulas are given in Reference 62.

Moody-Stauffer Formula In 1925, L. F. Moody and F. Stauffer independently developed a formula that was later modified by Pantell to the form

$$\left(\frac{1 - \eta_h}{1 - \eta'_h}\right) \left(\frac{\eta'_h}{\eta_h}\right) = \left(\frac{D'}{D}\right)^n \quad (35)$$

where η_h = hydraulic efficiency, discussed previously, and D = impeller diameter. Primed quantities refer to the model, and n is a constant to be determined by tests. The model must be tested with the same liquid that will be used in the prototype; that is, cold water in most practical cases. The original formula contained a correction for head, which is negligible if $H' \geq 0.8H$, and this requirement is now virtually mandatory in commercial practice. The meager information available indicates $0.2 \geq n \geq 0.1$ approximately, with the higher value currently favored. Improvements in construction and testing techniques very likely will move n toward lower value in the future. The Moody-Stauffer formula has been widely used since first publication. In practice, both η'_h and η_h are usually replaced by the overall efficiencies η' and η , respectively, because of the difficulty in determining proper values for the mechanical and volumetric efficiencies (see Eq. 11).

Rütschi Formulas The general form of several empirical formulas due to K. Rütschi⁶² and others was originally given as

$$\eta_h = \frac{f}{f'} \eta'_h \quad (36)$$

where η_h and η'_h are the hydraulic efficiencies of the prototype and model, respectively, and f and f' are values of an empirical f function for both the prototype and the model. The f function was obtained from tests of six single-stage pumps. $n_s < 2000$ (0.732) and is shown in Figure 58 based on the *eye diameters* D_o of the pumps in *millimeters*. Thus the f function depends on actual size in addition to scale ratio. The extrapolated portion of the curve, shown dashed in Figure 58, checked well with values for a model and large prototype, shown by E' and E , respectively. One of several formulas that have been proposed to fit the curve in Figure 58 is, in SI units,

$$f = 1 - \frac{3.15}{D_o^{1.6}} \quad (37)$$

FIGURE 58 The f function for the Rüttschi formula (to obtain D_o in inches, multiply by 0.03937) (References 13 and 62)

FIGURE 59 Chart for the solution of the Rüttschi formula (to obtain D_o in meters, multiply by 0.3048) (Reference 62)

where the eye diameter D_o is in centimeters or, in USCS units,

$$f = 1 - \frac{0.0133}{D_o^{1.6}} \quad (38)$$

where D_o is in feet. Figure 59 gives a graphical solution of Eq. 38. The Society of German Engineers (VDI) has adopted a slightly modified version of the Rüttschi formula as standard. Rüttschi later recommended, in discussion of Reference 62, that the internal effi-

ciency $\eta_i = \eta/\eta_m$ be used instead of the hydraulic efficiency η_h in Eq. 45. The mechanical efficiency η_m will probably be very high for both model and prototype for most cases of interest, so good results should be obtained if the overall efficiency is used in Eq. 36.

Model-prototype geometric similarity should include surface finish and wearing ring or tip clearances, but this may be difficult or impossible to achieve. Anderson (see Section 2.1: Figure 10 and Reference 6) proposed a method that includes a correction for dissimilarity in surface finish.

OPERATION OF PUMPS AS TURBINES

Centrifugal pumps may be used as hydraulic turbines in some cases where low first cost is paramount. Because the pump has no speed-regulating mechanism, considerable speed variation must be expected unless the head and load remain very nearly constant. Some speed control could be obtained by throttling the discharge automatically, but this would increase the cost, and the power lost in the throttle valve would lower the overall efficiency.

Pump Selection After the head, speed, and power output of the turbine have been specified, it is necessary to select a pump that, when used as a turbine, will satisfy the requirements. Assuming that performance curves for a series of pumps are available*, a typical set of such curves should be normalized using the head, power, and flow rate of the best efficiency point as normal values. These curves will correspond to the right part of Section 1 of either Figure 52 or 53. In normalizing the power P , let $p = P/P_n$ and the curve of p/ν^3 will be identical with the curve of m/ν^2 in Figure 52 or 53. The normalized curves may be compared with the curves in Sections 1 of Figures 52 and 53 to determine which curves best represent the characteristics of the proposed pump. When a choice has been made, the approximate turbine performance can be obtained from the corresponding figure of Figures 60 to 63.

EXAMPLE Assume that the turbine specifications are $H_T = 20$ ft, $P_T = 12.75$ hp and $n = 580$ rpm, and that the characteristics of the DeLaval L10/8 pump are representative of a series of pumps from which a selection can be made. The turbine discharge Q_T in gallons per minute after substituting the above values is

$$Q_T = \frac{3960P_T}{H_T\eta_T} = \frac{2520}{\eta_T} \quad (39)$$

FIGURE 60 Dimensionless characteristic curves for DeLaval L 10/8 pump, constant-discharge turbine operation (Reference 63)

*It is assumed that turbine mode characteristics of the proposed pump are not available when the initial selection is made.

FIGURE 61 Dimensionless characteristic curves for Voith pump, constant-discharge turbine operation (Reference 63)

FIGURE 62 Dimensionless characteristics curves for Peerless 10MH pump, constant-discharge turbine operation (Reference 63)

FIGURE 63 Dimensionless characteristic curves for Peerless 10PL pump, constant-discharge turbine operation (Reference 63)

where η_T is turbine efficiency, shown in Figure 60. Only the normal values Q_n , H_n , P_n , and so on, are common to the curves of both Figures 52 and 60, so these alone can be used in selecting the required pump. Values of ν/q , h/q^2 , and η_T are read from the curves of Figure 60 and corresponding values of Q computed by Eq. 39. Values of Q_n and H_n are then given by

$$Q_n = Q(\nu/q) \quad (40)$$

$$H_n = \frac{H(\nu/q)^2}{h/q^2} = \frac{20(\nu/q)^2}{h/q^2} \quad (41)$$

FIGURE 64 Head-flow curves of the pump selection (ft \times 0.3048 = m; gpm \times 0.06309 = l/s) (Reference 63)

For example, in Figure 60 at $\nu/q = 0.700$, read $h/q^2 = 0.595$ and $\eta_T = 0.805$. By Eq. 39, $Q_T = 2520/0.805 = 3130$ gpm; by Eq. 40, $Q_n = (3130)(0.700) = 2190$ gpm; and by Eq. 41, $H_n = (20)(0.700)^2/0.595 = 16.5$ ft. In a similar manner, the locus of the best efficiency points for an infinite number of pumps, each having the same characteristics as shown in Figures 52 and 60, is obtained, and each pump would satisfy the turbine requirements. This locus of best efficiency points is plotted as curve A in Figure 64.

The head curve for a DeLaval L 16/14 pump having a 17-in-diameter impeller tested at 720 rpm is shown as curve B in Figure 64. The best efficiency point was found to be at $Q_n = 3500$ gpm and $H_n = 37.2$ ft. The locus of the best efficiency points for this pump for different speeds and impeller diameters is given by Eqs. 12 as

$$H_n = 37.2 \left(\frac{Q_n}{3500} \right)^2 = \frac{3.04}{10^6} Q_n^2 \quad (42)$$

and is shown by curve C in Figure 64. Curve C intersects curve A at two points, showing that the L 16/14 pump satisfies the turbine requirements. Only the intersection at the higher turbine efficiency is of interest. At this point, $Q_n = 2490$ gpm and $H_n = 18.8$ ft. Because the turbine speed was specified to be 580 rpm, the required impeller diameter is given by Eqs. 12 as

$$D = \frac{(17)(2490/3500)}{580/720} = 15 \text{ in}$$

or by

$$D = \frac{17\sqrt{18.8/37.2}}{580/720} = 15 \text{ in}$$

The computed head curve for the 15-in-diameter impeller at 580 rpm is shown as curve D in Figure 64. The turbine discharge is 3200 gpm from Eq. 39 with $\eta_T = 0.787$.

The optimum solution would be to have Curve C tangent to Curve A at the point corresponding to maximum turbine efficiency, in this case $\eta_T = 0.812$. Because this

would require a smaller pump, Curve *E* in Figure 64 shows a head curve for a K 14/12 pump, which was the next smaller pump in the series. Curve *F*, the locus of the best efficiency points, does not intersect Curve *A*, showing that the smaller pump will not satisfy the turbine requirements. It is important to note that the turbine head, 20 ft, specified for this example was assumed to be the net head from the inlet to outlet flange of the pump when installed and operated as a turbine.

The procedure outlined above should lead to the selection of a pump large enough to provide the required power. However, it probably will be necessary to apply the affinity laws over such wide ranges of the variables that the usual degree of accuracy should not be expected. Considerable care should be exercised if it becomes necessary to interpolate between the curves of Figures 60 to 63. The computed performance will very likely differ from the results of subsequent tests. The curves of Figure 60 may be converted to show the constant-head characteristics of the L 16/14 pump when installed and operated as a turbine. Details of the method of computation are given in Reference 63, and the computed characteristics are shown in Figure 65.

A comprehensive study by Acres American^{64,65} led to a computer program to aid in selecting a pump to meet specific requirements when operating in the turbine mode. Known pump characteristics are entered in the program according to a specified format. The computer compares them with stored characteristics of pumps for which turbine mode characteristics are known and provides estimated turbine mode characteristics for the proposed pump. Vols. I and III of Reference 64 describe the method of computation and give complete instructions for using the program.

Optimized Hydraulic Turbines A logical outgrowth of applying pumps as hydraulic turbines is the optimization of these machines as turbines. Several points of efficiency improvement have been demonstrated over that of pumps running in reverse as turbines.⁶⁶ The fluid accelerates through both the stator or nozzles and the turbine wheel or runner, whereas it decelerates through the same elements when they are acting as impeller and diffuser or volute in the pumping mode. If the fluid never has to decelerate

FIGURE 65 Computed constant-head turbine characteristics for DeLaval L 16/14 pump ($\text{gpm} \times 0.06309 = \text{l/s}$; $\text{hp} \times 0.7457 = \text{kW}$) (Reference 63)

because the turbine will never be used as a pump, the nozzles and runner can be designed to produce more aggressive and efficient acceleration in shorter distances than if the same machine is simply a pump being used as a turbine. If it is a radial-inflow runner, the resulting optimized turbine wheel employs a radial blade (with a blade angle $\beta = 90$ deg. from the tangential direction) at the outer diameter (inlet). This outer diameter is about 75% of the diameter of the impeller of the pump-as-turbine, which further improves the efficiency by reason of the reduction of the disk friction drag of the runner. Design and application of both approaches is explained and compared in Reference 67. Many of the applications of these hydraulic turbines are for power recovery in the pressure let-down processes that occur in petroleum refining. Another variable is introduced in such processes; namely, the evolution of large volumes of dissolved gas as the pressure decreases through successive stages or portions of the turbine. This phenomenon affects the performance of hydraulic turbines for such applications because somewhat more power is produced when gas evolves from the liquid than when a single-phase liquid flows through the turbine at the same pressure drop and mass flow rate.⁶⁸

VORTEX PUMPS

A typical vortex pump is shown in Figure 66.* The ability of this type of pump to handle relatively large amounts of suspended solids as well as entrained air or gas more than offsets the relatively low efficiency. Table 10 lists performance data for four typical vortex pumps and four radial-flow centrifugal pumps of nearly the same head and flow rate. Figure 67 shows the head characteristics of a typical vortex pump with impellers of different diameters together with curves of constant efficiency and constant *NPSH*. Power curves for the same impellers are shown in Figure 68.

Curves for a conventional radial-flow pump have been added for comparison in Figures 67 and 68. Note that the head of the vortex pump does not decrease as rapidly with an increasing flow rate as does the head of the conventional pump. The power requirement of the vortex pump increases almost linearly with an increasing flow rate, whereas the power required by a conventional pump of about the same specific speed reaches a maximum and then decreases with the increasing flow rate.

Thus if the motor of the vortex pump has been selected to match the power required at the normal flow rate for best efficiency, it will be overloaded if the pump operates much beyond that point.

CENTRIFUGAL PUMP HYDRAULIC PERFORMANCE AND DIAGNOSTICS

WARREN H. FRASER

Any successful mathematical model of the mechanics of head generation in centrifugal pumps should do more than just make accurate predictions of pump performance; it should also be capable of identifying the cause of operational difficulties. Unlike mechanical malfunctions, which can be detected, analyzed, and corrected, many of the problems caused by hydraulic forces cannot be corrected in the mechanical sense—they are the unavoidable side effects of head generation in a rotating pressure field. For example, a thrust bearing may fail from lack of lubrication, from misalignment, or because an under-rated bearing has been used. These are mechanical failures that can be corrected. A thrust bearing may also fail from a complex pattern of dynamic loading that reflects pressure pulsations of high intensity and a broad spectrum of frequencies during operation at reduced flow. This is an example of a failure from hydraulic causes and can be corrected only by resorting to an oversized bearing or modifying the operation of the pumping system to avoid low-flow operation.

Whenever a consistent correlation can be made between the known dynamics of head generation and operational problems, it is possible to devise a strategy to improve operation and reduce mechanical failures. The most significant problems caused by hydraulic dynamic forces can be listed as follows.

CAVITATION

Cause and Effect Cavitation is the formation of vapor bubbles in any flow that is subjected to an ambient pressure equal to or less than the vapor pressure of the liquid being pumped. Cavitation damage is the loss of material produced by the collapse of the vapor bubbles against the surfaces of the impeller or casing. Formation of these bubbles cannot occur if the net positive suction head supplied, or *NPSHA*, exceeds the *NPSH* required for

cavitation inception. This *NPSH* inception value is usually significantly higher than the usually mentioned *NPSH* required, or *NPSHR*, which is based on a certain amount of cavitation being present to create a prescribed deviation in pump performance.

Diagnosis from Pump Operation Pump operation in the presence of sufficient cavitation activity will reduce both the total head and the output capacity. A steady crackling noise in and around the pump suction indicates cavitation. A random crackling noise with high-intensity knocks indicates suction recirculation but does not indicate a degradation of performance if *NPSHA* is greater than *NPSHR*. The random crackling is the unsteady occurrence of cavitation that generally accompanies suction recirculation, which, in turn, is an unsteady phenomenon.

Diagnosis from the Visual Examination of Surface Damage Cavitation damage from inadequate *NPSH* (that is, $NPSHA < NPSHR$) occurs on the low-pressure or the visible surface of the impeller inlet vane.

Instrumentation A suction gage or manometer in the pump suction can be used to determine whether the *NPSH* available is equal to or greater than the *NPSH* required from the manufacturer's rating curve (*NPSHR*).

Corrective Procedures If additional *NPSH* cannot be supplied, the capacity of the pump should be reduced until the required *NPSH* is equal to or less than the available *NPSH*. If this is not possible, impeller improvement may be necessary. This may be accomplished on some impeller designs by reworking the geometry or impeller surface finish to reduce losses, improve flow characteristics, or increase the flow inlet area (thus lowering impeller inlet velocity). If this is not possible, consideration should be given to replacing the impeller (first stage or suction impeller on multistage pumps) with one of improved suction performance. The pump manufacturer should be consulted to determine the most satisfactory course of action.

SUCTION AND DISCHARGE RECIRCULATION

Cause and Effect Recirculation occurs at reduced flows and is the reversal of a portion of the flow back through the impeller. Recirculation at the inlet of the impeller is known as *suction recirculation*. Recirculation at the outlet of the impeller is *discharge recirculation*. Suction and discharge recirculation can be very damaging to pump operation and should be avoided for the continuous operation of pumps of significant energy level or pressure rise per stage.

Diagnosis from Pump Operation Suction recirculation will produce the previously mentioned loud crackling noise in and around the suction of the pump. Recirculation noise is of greater intensity than the noise from low-*NPSH* cavitation and is a random knocking sound. Discharge recirculation will produce the same characteristic sound as suction recirculation except that the highest intensity is in the discharge volute or diffuser.

Diagnosis from Visual Examination Suction and discharge recirculation produce cavitation damage to the pressure side of the impeller vanes. Viewed from the suction of the impeller, the pressure side would be the invisible, or underside, of the vane. Figure 1 shows how a mirror can be used to examine the pressure side of the inlet vane for cavitation damage from suction recirculation. This is unlike cavitation damage from inadequate *NPSH* that occurs on the low pressure surface of the inlet vanes. Damage to the pressure side of the vane from discharge recirculation is shown in Figure 2. Guide vanes in the suction may show cavitation damage from impingement of the backflow from the impeller eye during suction recirculation. Similarly, the casing tongue or diffuser vanes may show cavitation damage on the impeller side from operations in discharge recirculation.

FIGURE 1 Examining the pressure side of the inlet vanes for suction recirculation damage

FIGURE 2 Damage to the pressure side of the vane from discharge recirculation

Instrumentation The presence of suction or discharge recirculation can be determined by monitoring the pressure pulsations in the suction and in the discharge areas of the casing. Piezoelectric transducers installed as close to the impeller as possible in the suction and in the discharge of the pump can be used to detect pressure pulsations. The data may be analyzed with a spectrum analyzer coupled to an XY plotter to produce a record of the

FIGURE 3 Pressure pulsations versus capacity

pressure pulsations versus the frequency for selected flows. Figure 3 shows a typical plot of pressure pulsations versus capacity. As can be seen, a sudden increase in the magnitude of pressure pulsations indicates the onset of recirculation.

The onset of suction recirculation can be determined by an impact head tube (or pitot tube) installed at the impeller eye, as shown in Figure 4. With the tube directed into the eye, the reading in the normal pumping range is the suction head minus the velocity head at the eye. At the point of suction recirculation, however, the flow reversal from the eye impinges on the head tube with a rapid rise in the gage reading.

Corrective Procedures Every impeller design has specific recirculation characteristics. These characteristics are inherent in the design and cannot be changed without modifying the design. An analysis of the symptoms associated with recirculation should consider the following as possible corrective procedures:

1. Increase the output capacity of the pump.
2. Install a bypass between the discharge and the suction of the pump.
3. Substitute an improved material for the impeller that is more resistant to cavitation damage.
4. Modify the impeller design.

FIGURE 4A and B Installation of the impact head tube to detect suction recirculation during (a) normal flow and (b) recirculation flow

AXIAL THRUST

Cause and Effect Axial thrust is the thrust imposed in the direction of the shaft. It may occur in either the inboard or the outboard direction and is usually composed of a dynamic cyclic component superimposed on a steady-state load in either direction. The dynamic cyclic component increases in the recirculation zone and may impose excessive stresses in the shaft, which could ultimately result in failure from metal fatigue. The static component may impose an excessive load in the thrust bearing, causing unacceptable bearing temperatures. The majority of thrust-bearing failures are caused by fatigue failure of the bearing components from dynamic cyclic axial loads.

Diagnosis from Pump Operation High axial loads usually produce high thrust-bearing temperatures and short thrust-bearing life.

Diagnosis from Visual Examination of Damage

BEARING DAMAGE Static thrust in excess of the bearing rating will cause cracking of the balls or rollers and of the race in rolling element bearings and metal scorings of the shoes in tilting-pad bearings. Bearing failure from dynamic loading in excess of the bearing rating will cause fatigue failures of the balls or rollers and race in rolling element bearings.

It is important to differentiate clearly between static load failure and fatigue failure. This can be done by examination of a cross section of the failure zone under the microscope. Fatigue failure from dynamic loading will show a hammering effect caused by points of impact. Fatigue failure from excessive static loading will show metal fatigue without the hammering effect of impact loading.

SHAFT FAILURE Shaft failure at the outboard, or unloaded, end of the shaft in multistage or double-suction pumps may be a fatigue failure in tension resulting from the high cyclic stresses induced in the shaft when the pump is operated in the discharge recirculation zone. Axial cyclic stresses can be reduced by increasing the pump output or, if this is not possible, by installing a recirculation line to bypass sufficient flow to move the pump total flow rate beyond the point where damaging discharge recirculation occurs. The pump manufacturer can advise the recommended minimum continuous flow for a specific pump design.

FIGURE 5 Load cell to monitor axial load

Instrumentation Displacement-type pickups should be used to determine the axial movement of the shaft relative to the bearing housing. The deflection of the thrust bearing housing can be determined by seismic instruments. Axial loading of the tilting-shoe type of thrust bearing can be monitored by a load cell permanently installed in the leveling plate. A typical installation is shown in Figure 5.

Corrective Procedures To determine the most effective procedure to correct axial thrust problems, it is necessary to determine whether the loads are static, dynamic, or a combination of both. If it is a static failure, the thrust can usually be reduced by restoration of the internal clearances. Most shaft and bearing failures from axial thrust, however, are fatigue failures. If the failure is a fatigue failure, the loading can usually be decreased by increasing the capacity of the pump. If this is not possible, shaft failures can be reduced by substituting a shaft material of higher endurance limit. Rolling element bearing failures can be addressed in large, between bearings pumps by substituting a tilting-shoe type of thrust bearing. The high cyclic axial forces are better absorbed in the oil film of the tilting-shoe bearing than in the rolling element bearing.

RADIAL THRUST

Cause and Effect Radial thrust is the thrust imposed on the pump rotor and directed toward the center of rotation of the shaft. The forces are usually composed of a dynamic cyclic component superimposed on a steady-state load. The dynamic cyclic component increases rapidly at low-flow operation when the pump is operating in the recirculation zone. The static load also increases with low- and high-flow operation, with the minimum value at or near the maximum efficiency capacity.

Diagnosis from Pump Operation High radial thrust is difficult to determine from pump operation. Persistent packing or mechanical seal problems may indicate excessive shaft deflection from radial loads. As in the case of high axial loads, high radial loads may produce high bearing temperatures with reduced life.

Diagnosis from Visual Examination of Damage

BEARING DAMAGE Static radial loads in excess of the bearing rating will cause cracking of the balls or rollers and the races in rolling element bearings. In the case of sleeve bearings, the bearing metal will be worn in one direction only and the journal will be worn uniformly. If the opposite is true (that is, the bearing is worn uniformly and the journal excessively in one direction), the cause of the failure is most likely unbalance or a bent shaft and not excessive bearing loads.

SHAFT FAILURES Shaft failures from excessive radial loads usually occur at the midpoint of the shaft span in double-suction or multistage pumps. In the case of end-suction pumps, shaft failures usually occur at the shoulder of the shaft, where the impeller hub joins the shaft sleeve, or at the location of the highest stress concentration, if elsewhere.

Instrumentation It is difficult to devise instrumentation to determine excessive radial loading of the shaft and bearings. Temperature rise of the bearings may or may not be symptomatic of excessive radial loading. High bearing temperatures may occur from misalignment, inadequate lubrication, or excessive axial loading of the thrust bearing. These causes should be eliminated before concluding that the radial loads are excessive.

Corrective Procedures Most bearing and shaft failures caused by excessive radial loads occur when the pump operates at low flow rates. Radial loads can be reduced by operating the pump at higher capacities or by installing a bypass from the pump discharge back to the pump suction or suction source. For pumps handling water, the life of the shaft may be extended by substituting a martensitic stainless (13% chrome) steel shaft for carbon steel. If there are signs of corrosion as well as fatigue failure, an austenitic stainless steel shaft may also be considered. Physical properties should be evaluated carefully, as the endurance limit of the 300 series steels may be lower than that of chrome steels in fresh water. For liquids other than water, the endurance limit of the shaft material in the liquid being pumped may be a significant determining factor in the life of the shaft in the presence of high dynamic loading.

PRESSURE PULSATIONS

Cause and Effect Pressure pulsations are present in both the suction and the discharge of any centrifugal pump. The magnitude and frequencies of the pulsations depend upon the design of the pump, the head produced by the pump, the response of the suction and discharge piping, and the point of operation of the pump on its characteristic curve. The observed frequencies in the discharge may be the running frequency, the vane passing frequency, or multiples of each. In addition, random frequencies with pressure pulsations higher than either the rotating or the vane passing frequencies have been observed. The cause of these random frequency pulsations is sometimes difficult to determine. System resonance, acoustic behavior, eddies from valves and poor upstream piping, and so on, are sometimes involved. However, such random pressure pulsations should not be dismissed as spurious or irrelevant data in any analysis of symptomatic operational problems.

The observed frequencies in the pump suction are much lower than in the discharge. Typical frequencies are in the order of 5 to 25 cycles/s, and they do not appear to bear any direct relation to the rotational speed of the pump or the vane passing frequency.

Diagnosis from Pump Operation In most pumping installations of 435 lb/in² (3MPa) [that is, 1000 ft (305 m) of head in water] or less of head per stage, there is little outward

manifestation of pressure pulsations during normal pumping operation. Other than for specialized applications, such as white water pumps for paper machines (where the discharge pressure pulsations may affect the quality of the paper) or quiet pumps in marine service, there are few external symptoms of internal pressure pulsations. For high-head pumps, however, suction and discharge pressure pulsations may cause instability of pump controls, vibration of suction and discharge piping, and high levels of pump noise.

Diagnosis from Visual Examination of Damage In the case of high-head pumps, any failure of internal pressure-containing members should be investigated with consideration given to the possibility that the failures are fatigue failures from internal pressure pulsations. Examination of the fracture will determine whether the failure is a fatigue failure or not. Fatigue failures may have one or more origins. Characteristic markings, known as striations, are often present on the fracture surface. Metallurgical examination of the fracture surface will also disclose striations on a microscopic scale. These markings represent growth of the crack front under cyclic stress.

If it is a fatigue failure, the cause can usually be traced to high cyclic stress induced in the pressure-containing member from high-frequency pressure pulsations.

Instrumentation Pressure pulsations are usually measured with piezoelectric pressure transducers and recorded as peak-to-peak pressure pulsations over a broad frequency band. Recorded on tape or strip charts, a spectral analysis may be performed for any operating condition.

Corrective Procedures A spectral analysis of the pressure pulsations at the suction and at the discharge of the pump is necessary before a strategy for corrective procedures can be developed. After the spectral analysis is available, problems associated with pressure pulsations can usually be reduced by implementing the procedures shown in Table 1.

TABLE 1 Corrective procedures for various problems

| Problem | Corrective procedure |
|--|---|
| 1. Vibration of suction or discharge piping | <ol style="list-style-type: none"> Search for responsive resonant frequencies in the piping or supports. If any part of the system responds to the frequency of the pressure pulsations, alter the system to shift the resonant frequencies. If possible, increase the output of the pump by changing the mode of operation or by installing a bypass from the discharge to the suction of the pump. If the piping responds to the vane passing frequency of the pump, the impellers can be replaced with a unit containing either one fewer or one more vane. |
| 2. Instability of pump controls | <ol style="list-style-type: none"> If possible, increase the output of the pump by changing the mode of operation or by installing a bypass from the discharge to the suction of the pump. Install acoustical filters to reduce the magnitude of the pressure pulsations. |
| 3. Fatigue failure of internal pressure-containing components of the pump from pressure pulsations | <ol style="list-style-type: none"> If possible, increase the output of the pump by changing the mode of operation or by installing a bypass from the discharge to the suction of the pump. Redesign the failed components to reduce the induced cyclic stresses to below the endurance limit of the material. If the spectral analysis shows that the maximum pressure pulsations correspond to the vane passing frequency of the impeller, the impeller can be replaced by one having either one fewer or one more vane of the same design. |

2.3.3

CENTRIFUGAL PUMP MECHANICAL PERFORMANCE, INSTRUMENTATION, AND DIAGNOSTICS

CHARLES JACKSON
JAMES H. INGRAM

MECHANICAL PERFORMANCE

The mechanical performance of a pump would imply only the rotating mechanical masses, with no consideration given to hydraulic (process) effects. The rotating masses (impellers, sleeves, nuts, coupling, bearings, seals, and so on) can be examined as pure mechanics. A person concerned with mechanical performance should be intimately familiar with pump design, construction, and maintenance to be successful.

In discussing the mechanical performance of centrifugal pumps, two examples will be used. The first will be a horizontal, 500-hp (373-kW), single-stage (overhung impeller) American Petroleum Institute (API) process pump. The second will be a six-stage, horizontal, 1000-hp (746-kW), multistage boiler-feed pump.

Normally, the rotor dynamics will involve (a) a review of the shaft stiffness of the bearings and structure, (b) a mass model of the rotor, and (c) a critical speed analysis with mode shapes of the rotor or shaft.

SINGLE STAGE PUMP

An $8 \times 6 \times 13$ pump is operating on water at 3550 rpm with a design flow of 2500 gpm (567 m³/h) at 600 ft (183 m) total head, 1.0 sp. gr., requiring approximately 500 hp (373 kW). The pump operated extremely rough, and the bearings and bearing housing failed. The impeller weighs 61.4 lb (27.9 kg).

If the impeller is fitted on the shaft with an eccentricity of 0.002 in (0.051 mm), a calculated centrifugal force F_e of 44 lb (196 N) would cause a deflection of 0.0026 in (0.066 mm) from

$$y = wl^3/3EI$$

where w = weight (force) of impeller, lb (N)

l = length of overhang, in (m)

E = modules of elasticity, lb/in² (N/m² or Pa)

I = shaft section moment of inertia, in⁴ (mm⁴)

This pump has a 5212 line bearing and tandem mounted (DB) 7311DB angular contact thrust bearings (40° contact angle). An extremely loose fit of the radial bearing in the bearing housing could cause the outer race to spin, which could cause a vibration equal to twice the rotation frequency. Interference fitting could lead to radial bearings' accepting thrust (for which many are not designed) from thermal expansion of the shaft or from the thrust bearing.

Frequencies Generated The following data and definitions are needed to compute the frequencies generated by defective bearings¹:

rpm = revolutions per minute

rps = revolutions per second

FTF = fundamental train frequency, Hz

BPF_I = ball passing frequency of inner race, Hz

BPF_O = ball passing frequency of outer race, Hz

BSF = ball spin frequency, Hz

Bd = ball or roller diameter, in (mm)

Nb = number of balls or rollers

Pd = pitch diameter, in (mm)

\emptyset = contact angle

The formulas are

$$\text{rps} = \frac{\text{rpm}}{60}$$

$$FTF = \frac{\text{rps}}{2} \left(1 - \frac{Bd}{Pd} \cos \emptyset \right)$$

$$BPF_1 = \left(\frac{Nb}{2} \text{ rps} \right) \left(1 + \frac{Bd}{Pd} \cos \emptyset \right)$$

$$BPF_O = \left(\frac{Nb}{2} \text{ rps} \right) \left(1 - \frac{Bd}{Pd} \cos \emptyset \right)$$

$$BSF = \left(\frac{Pd}{2Bd} \text{ rps} \right) \left[1 - \left(\frac{Bd}{Pd} \right)^2 \cos^2 \emptyset \right]$$

The pitch diameter is the diameter measured across the bearing from ball or roller center to ball or roller center. The contact angle is measured from a line perpendicular to the shaft to the point at which the balls or rollers contact the race. The contact angle of a deep groove ball bearing is zero.

It is necessary to distinguish between the ball frequency and the impeller vane passing frequency, which is 17,750 cpm (5 vanes \times 3550 rpm \times 1 casing cutwater) for this example. The mode shape of the pump shaft is conical (pivotal) in the first mode of a cantilevered shaft mount. The stiffness map of the rotor looks like that shown in Figure 1.

This pump has two design faults, as can be seen from the stiffness map. The first is that an excessively large coupling is used. This heavy overhung mass at the coupling forces the first shaft resonance to be very near the pump operating speed. Normally, the shaft in this type of pump is considered to be "rigid," that is, operating safely below the first undamped shaft resonance. In this case, the pump is affected by two negatively additive errors. The

FIGURE 1 Undamped critical speed map of single-stage overhung pump, comparing normal and heavy coupling weights (lb/in \times 175 = N/m)

TABLE 1 Logic of spring equivalent stiffness K_e

| SPRING | ELECTRICAL RESISTOR EQUIV ANALOG | EXAMPLES OF VARIATIONS (K_e) | | |
|---|---|----------------------------------|--------------------------|--------------------------|
| | | | | |
| $1/K_e = \frac{1}{K_b} + \frac{1}{K_s}$ | $1/R_e = \frac{1}{R_b} + \frac{1}{R_s}$ | $K_e = 91\text{k lb/in}$ | $K_e = 83\text{k lb/in}$ | $K_e = 50\text{k lb/in}$ |

K_b = STIFFNESS OF BEARING, lb/in (N/m) N/m = 175 X lb/in
 K_s = STIFFNESS OF SUPPORT, lb/in (N/m)
 K_e = EQUIVALENT STIFFNESS

NOTE: SPRINGS IN PARALLEL: SIMPLY ADD, AS DOES
ELECTRICAL RESISTANCE IN SERIES: $K_e = K_b + K_s$

heavy mass coupling effect is compounded by a weak baseplate that is not properly grouted, leaving a void under the pump supports. In rotor (shaft) supports, two spring supports in series reciprocally add, similar to electric resistors in parallel (Table 1).

The effective stiffness is

$$K_e = \frac{1}{1/K_b + 1/K_s}$$

If the bearing stiffness K_b is 2.5×10^6 lb/in (4.4×10^6 N/m) and the support stiffness K_s is low; that is, 7.0×10^5 lb/in (1.2×10^5 N/m), the effective stiffness is 5.47×10^5 lb/in (9.57×10^7 N/m), which moves the first mode resonance from 4300 cpm to 3550 cpm, which is the running speed of the pump.

The mode shapes of the rotor are shown in Figures 3 and 4. An animated display is used to better show the rotor gyrations in synchronous whirl. The first modes are shown with a

FIGURE 4 Synchronous critical speed summary with first three mode shapes of a single-stage overhung pump with light coupling of 15 lb (6.8 kg) and rigid or flexible foundation. Rotor weight = 110.4 lb (50 kg); rotor length = 30.3 in (77.0 cm); number of stations = 22; number of bearings = 2. (a) Rigid support, modes 1, 2, and 3 respectively: 4717, 58,482, and 67,522 rpm; (b) flexible support, modes 1, 2, and 3 respectively: 4085, 21,251, and 40,036 rpm. (lb \times 0.454 = kg; lb/in \times 175 = N/m)

lighter, normal, and correct coupling (15 lb; 6.8 kg). Figure 2 shows the mathematical model of this pump with the impeller at station 2, the radial bearing at station 11 at 2.5×10^6 lb/in (4.4×10^8 N/m) stiffness, the outboard thrust/radial bearing at station 18 at 3.5×10^6 lb/in (6.1×10^8 N/m) and the coupling at station 21.

Figure 3a, obtained from a finite element computer analysis of the mathematical model in Figure 1, shows the first mode with a rotor weight of 110.4 lb (50 kg), a rotor length of 30.3 in (77.0 cm), and a first mode undamped resonance (critical) of 4717 cpm. This is a pivotal mode, with 100% of the normalized motion at the impeller end. Any motion at the antifriction bearings is greatly restrained.

Figure 3b shows the second resonance mode, at 53,482 cpm, which is not to be encountered. The coupling motion is now the greatest motion.

Figure 3c shows the third mode, at 67,522 cpm.

Figure 4a shows an overlay of all three modes with a summary of the criticals, the modal mass, and the relative strain energy (91) in the shaft at station 10 (impeller side of radial bearing). A lesser strain energy is at the radial bearing (station 11).

Figure 4b summarizes what happens to critical speed modes if either a more *flexible* bearing or a soft structure is provided intentionally or unintentionally. Also note that the criticals are lowered significantly and the strain energy is transferred more from the shaft into the bearings; that is, strain values under the *U-shaft* column are less than under *U-bearing* column. The first critical is 4085 cpm at a pump speed of 3550 rpm (+15%). A 15% margin of separation may be close enough to excite (cause a rise in vibration) the rotor if the resonance response envelope is too wide. However, this is unlikely on antifriction bearings (spiky/narrow response), but possible on sleeve bearings (low/broad response).

Figure 5a is a summary which shows the response of a rigid support and an *excessively heavy* (62 lb = 28 kg) coupling, which is as heavy as the impeller. Note that the first mode is again only slightly above the operating speed; that is, 4279 cpm compared with 3550 (+21%). The bearing stiffness is assumed to be the controlling stiffness. Many assume that the structure or base stiffness is one order above the bearing stiffness ($K_s = 10K_b$). This assumption that the bearing stiffness is the controlling stiffness variable is often a very poor assumption. The larger the pump size, the more this is true. That is why an $8 \times 6 \times 13$ pump was used as an example.

Further, the second mode, at 15,865 cpm, is in an area where the blade passing frequency ($5 \times 3550 = 17,750$ cpm) can easily excite this mode, given little variation in support stiffness. Figure 5b is a summary sheet that best illustrates the problem:

- The baseplate was improperly installed and grouted.
- The elastomeric coupling designed for low-duty, low-speed, and torsional damping was *too heavy*; that is, too much overhung weight.

Note that the first critical is in sympathy with the pump operating speed, which becomes intolerable with the operating time *limited* to one to two days, due to bearing failures.

The stiffness on antifriction bearings was determined from a program written by M. E. Leader of Monsanto, using values projected by an article written by F. F. Garguilo, DuPont.² The correction consisted of converting the 62-lb (28-kg) coupling to a 15-lb (6.8-kg) series dry flex disk-type coupling and stiffening the support by flushing the baseplate cavity with a degreasing fluid and pressure injection of epoxy to fill the baseplate voids.

It should be remembered that the blade passing frequencies will normally be the strongest exciting force. On this pump, the frequency is five times running speed (five vanes times each cutwater). Because there are two cutwaters, there can also be a frequency at 10 times running speed. The $5 \times$ frequency is shown on Figure 1. Also, this $5 \times$ frequency excitation could excite the second mode because the second mode critical could fall anywhere between the solid and dashed lines, depending on baseplate stiffness.

The instruments used in diagnosing this problem were force-effective seismic sensors (velocity or piezoelectric accelerometers). They are preferred for pumps, particularly those with antifriction bearings.

MULTISTAGE PUMP EXAMPLE

To show the mechanical rotor variations, a six-stage boiler-feed pump with a design capacity of 1250 gpm (284 m³/h), 2200 ft (670 m) total head, and driven by a 1000-hp (746-kW), two-pole motor has been selected. This pump utilizes interstage bushings as support bearings to the rotor. The contribution of these bushings as bearings will probably be less than might be assumed.

FIGURE 5 Synchronous critical speed summary with first three mode shapes of a single-stage overhung pump with heavy coupling of 62 lb (28 kg) and rigid foundation. Rotor weight = 157.4 lb (71.4 kg); rotor length = 30.3 in (77.0 cm); number of stations = 22; number of bearings = 2. (a) Rigid support, modes 1, 2, and 3 respectively: 4279, 15,865, and 64,970 cpm; (b) flexible support, modes 1, 2, and 3 respectively: 3580, 9339, and 35,565 cpm. (lb \times 0.454 = kg; lb/in \times 175 = N/m)

Pressure or seal leakage control bushings contribute rotor support if they are long. The hot feedwater has very low viscosity and little damping. The bearing stiffness will be relative to the eccentricity ratio of the shaft in the bushings. An eccentricity ratio of unity (maximum) implies that the shaft is rubbing directly on its bushing.

The impeller weight is increased by the water trapped in each impeller. Many pump manufacturers improperly list pump undamped critical speeds from *dry* pump data or calculations. The bushings, labyrinths, and wear rings all contribute to the actual critical speed. Also, bearing housing resonances are more common than expected.

FIGURE 6 Undamped critical speed map of multistage boiler-feed pump with plain journal bearings ($\text{lb/in} \times 175 = \text{N/m}$)

FIGURE 7 Rotor cross-section of multistage high-pressure boiler-feed pump with plain journal bearings. Rotor weight = 377.7 lb (171.3 kg), rotor length = 84.6 in (215 cm); number of stations = 47, number of bearings or bushings = 4 ($\text{in} \times 2.54 = \text{cm}$)

Figures 6 to 9 illustrate it in the same fashion as the previous example the design audit of a steam-turbine-driven, $4 \times 8 \times 10\frac{1}{2}$, six-stage, boiler-feed pump using hydrodynamic radial and thrust bearings. No problems were experienced with this pump.

A more complete listing of data from analysis is shown with an added breakdown of the rotor model and the output of the first, second, and third resonant modes. The first critical (rotor resonance) is now a cylindrical mode and not a conical mode, as previously seen for the overhung impeller of the single-stage process pump.

ALIGNMENT OF PUMPS AND DRIVERS

Outside of serious unbalance of pump components, there is no single contributor of poor mechanical performance more significant than poor alignment. Incorrect alignment between a pump and its driver can cause

- Extreme heat in couplings
- Extreme wear in gear couplings and fatigue in dry element couplings

FIGURE 8 First, second, and third resonant animated mode shapes of multistage high-pressure boiler-feed pump with plain journal bearings. Rotor weight = 377.7 lb (171.3 kg); rotor length = 84.6 in (215 cm); number of stations = 47; number of bearings or bushings = 4. (a) Mode 1: frequency = 2614 cpm; (b) mode 2: frequency = 5223 cpm; (c) modes: frequency = 8134 rpm. (in $\times 2.54 =$ cm)

- Cracked shafts and totally failed shafts, with failure due to reverse bending fatigue transverse to the shaft axis initiating at the change of section between the large end of the coupling hub taper and the shaft
- Preload on bearings (evident by an elliptical and flattened orbit resembling a deflated beach ball); pure asymmetry of vertical and horizontal vibration can be misleading because the bearing spring constants could vary greatly in the k_{yy} (vertical) and the k_{xx} (horizontal) axis.
- Bearing failures plus thrust transmission through the coupling, which can be totally locked (axial vibration checks across the coupling; that is, at each adjacent machine, will generally confirm this condition)

Significant changes in the cold nonrunning alignment of a pump and driver can take place if the temperature rise in each machine is different and if the piping imposes forces on the pump.

| No. UNITS | CRITICAL SPEED | | WMODE, lb | ITMODE, lb/in ² | KMODE, lb/in | DIM. STRAIN ENERGY | |

FIGURE 9 First three critical speed mode shapes of multistage high-speed boiler-feed pump superimposed (in × 2.54 = cm)

Therefore, alignment under actual operating conditions must be predicted or, if unknown, confirmed by instrumentation. In either case, an allowance must be made in the initial cold alignment to compensate for changes in alignment from cold idle to hot running.

There are several techniques for measuring cold and hot alignment. The cold alignment is generally measured by either face and rim (Figure 10) or reverse dial indicator (Figure 11) methods.

The face and rim method has a sensitivity advantage when the diameter of a coupling exceeds the indicator span of reverse indicator bracket tooling. This is rare, as the pump will generally have a spacer coupling and the reach of the reverse indicators can be increased by clamping onto the shaft behind each coupling half. The face and rim method would also have an advantage if either the driver or the gear could not be rotated, as it seems unlikely that the pump could not be rotated. In order to compensate for the measuring surface's not being circular or smooth, both shafts should be rotated together when using this method.

Disadvantages of Face and Rim Method

- 1. Diameters of the rim must be true (circular) and smooth and the face reading surface must be flat and smooth, unless both shafts are rotated together.
- 2. The driver and pump cannot float axially while a reading is being taken or an error will be introduced into the face (angular) reading. (A fixed axial stop will assist in reducing errors.)

Reverse Dial Procedure for Measuring Alignment (Hot or Cold) Several procedures have been suggested by various people to estimate or actually measure alignment while a pump is running at operating temperature. Some techniques are

- 1. Shutdown after temperatures have stabilized for “hot check” by dial indicators
- 2. Optical measurements cold to hot (A. J. Campbell, Compressor Engineering Corp., Houston)
- 3. Dodd bars (DynAlign) technique (B. Dodd, Chevron³)

Check for Angular Misalignment Dial indicator measures maximum longitudinal variation in hub spacing through 360° rotation.

1. Attach dial indicator to hub, as with a hose clamp; rotate 360° to locate point of minimum reading on dial; and then rotate body or face of indicator so the zero reading lines up with pointer.
2. Rotate both half couplings together 360°. Watch indicator for misalignment reading.
3. Driver and driven units will be lined up when dial indicator reading comes within maximum allowable variation for that coupling style. Refer to specific installation instruction sheet for the coupling being installed. Note: If both shafts cannot be rotated together, connect dial indicator to the shaft that is rotated.

Check for Parallel Misalignment Dial indicator measures displacement of one shaft center line from the other.

4. Reset pointer to zero and repeat operations 1 and 2 when either driven unit or driver is moved during aligning trials.
5. Check for parallel misalignment as shown. Move or shim units so parallel misalignment is brought within the maximum allowable variations for the coupling style.
6. Rotate couplings several revolutions to make sure no "end-wise creep" in connected shafts is measured.
7. Tighten all lockouts or capscrews.
8. Recheck and tighten all locknuts or capscrews after several hours of operation.

FIGURE 10 Face and rim dial indicator method (Courtesy Rexnord)

FIGURE 11 Model used for training machinist in the use of reverse dial indicator technique for alignment of machine shafts. Misalignment can be measured as parallel or angular offset.

4. Acculign bench mark gauges (I. Essinger, Shell Oil)
5. Water-cooled probe stands (C. Jackson, Monsanto)
6. Instrumented coupling (for example, Indikon)

Refer to Reference 4 for more specific information on the above techniques.

After measurements have been made and actual misalignment is determined for the hot running condition of the pump, the next step is to calculate the alignment correction required between machines to bring them into alignment during operation. Trial-and-error methods should be discouraged. Plotting actual shaft positions to scale allows one to graphically measure the required cold alignment corrections. Other methods—for example, those that can best be carried out with the aid of a programmable calculator—quickly and accurately calculate vertical, horizontal, inboard or outboard changes in machine positions to accomplish the correct cold alignment. See Reference 11 for a calculator program for both reverse dial and face and rim methods.

Offered here are a graphical procedure and an example for obtaining the desired alignment between a pump and driver for a case where the thermal growth has been estimated and a calculated cold alignment is desired to achieve the final alignment during operation.

The example is illustrated in Figure 12. Consider a steam-turbine-driven boiler-feed pump that has the following heat rise predictions by the manufacturers: steam end 0.002 in (0.051 mm), exhaust end 0.012 in (0.305 mm), pump inboard support 0.006 in

FIGURE 12 Alignment example of a turbine-driven boiler-feed pump with heat-rise data from the manufacturers plotted to calculate the desired cold alignment

FIGURE 13 Desired dial indicator readings corrected for indicator bar sag

FIGURE 14 Actual alignment readings

FIGURE 15 Dial readings corrected to position zero at top

FIGURE 16 Actual alignment readings corrected for indicator bar sag

FIGURE 17 Plot of absolute vertical shaft positions. It can be seen from the graph that a 0.019-in (0.483-mm) shim is required to raise the inboard end of the pump and a 0.035-in (0.889-mm) shim is required to raise the outboard end of the pump to compensate properly for thermal growth

(0.152 mm), and outboard bearing 0.004 in (0.102 mm). The horizontal length is laid on a graph with 1 div. = 1 in (25.4 mm). The vertical movement plots are laid out with 1 div. = 0.001 in (1 mil; 0.0254 mm).

Based on 0.001-in (0.0254-mm) sag (see Figure 19), the field readings needed to meet the above absolute requirements are shown in Figure 13.

The actual cold alignment is checked, and the reverse dial readings are as recorded in Figure 14. There are 0.125-in (3.175-mm) shims under all support feet. It is decided to move the pump rather than the turbine, and therefore the correct cold position of the pump must be calculated.

To correct the turbine dial readings to position zero at the top, simply add -12 to all four turbine readings (Figure 15). To correct for sag (see Figure 19 for explanation), *subtract* 1 from the left and right readings and 2 from the bottom reading (Figure 16). Finally, plot the absolute shaft positions on graph paper, leaving the turbine “in place,” so to speak, thereby determining two points across the 16-in (40.64-cm) indicator span to define *where* the pump shaft lies with *respect* to the turbine (Figure 17).

To plot the horizontal corrections, reduce the final horizontal readings *only* to zero on the least numerical reading, by adding 4 to the turbine readings and -5 to the pump reading, as shown in Figure 18.

Dial indicator readings can be in metric units and the scale in centimeters rather than inches. A scale of between 500:1 and 1000:1 is suggested. A 1000:1 scale is in use here (horizontal scale equals 1000 times vertical scale).

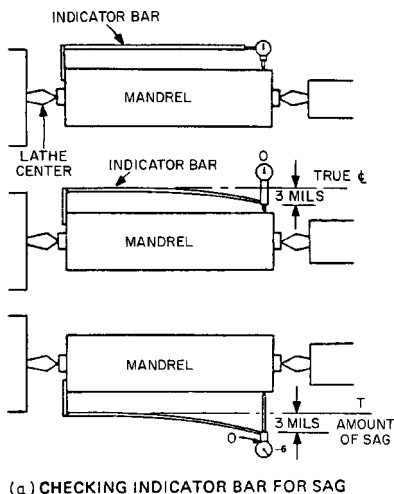

FIGURE 18 Required horizontal corrections

As shown in Figure 12, the driver and pump are purposely misaligned so actual operating temperatures will put the two shafts within acceptable limits. The acceptable limits for pump final alignment are 0.001 in/in (0.025 mm/mm) of coupling flex plane separation. If a spacer coupling is 5 in (13 cm) between flex planes on the flexible coupling, the shafts must be within 0.005 in (0.127 mm) vertical or horizontal offset. Pure angular misalignment in one plane is not desired, as it reduces the tolerance by 2:1 for gear couplings (dry coupling would have severe fatigue in one flex plane). The above limits should be reduced by one-half.

INSTALLATION SUGGESTIONS AND USE OF DIAL INDICATORS

1. Nonferrous shim packs should be installed under all feet of the pump and driver, particularly when installing a new pump. The amount should be 0.125 to 0.250 in (3.175 to 6.35 mm) in no more than three pieces to start; for example, one 0.125-in (3.175 mm) and two 0.0625-in (1.59-mm) full shims of stainless steel.
2. Motors have four feet generally, and any "soft foot" should be compensated first. A soft foot is one that is shorter than the other two or three feet, a condition that puts a twist or strain in the equipment. Simply place a dial indicator stem vertically against the motor foot and release the hold-down bolts sequentially around the unit, recording and retightening at each step. If a 0.002-in (0.050-mm) spring-up occurs on three feet, for example, and 0.006 in (0.152 mm) occurs on the fourth foot, add 0.004 in (0.10 mm) of shim to the fourth foot, eliminating the soft foot.
3. Provide low-sag tooling to reach over the coupling (coupling left in place) for reverse indicator alignment. A 0.001- to 0.0015-in (0.025- to 0.038-mm) sag is easy to accomplish on indicator reach bars.
4. Let the indicator indicate on its own bracket or bracket pin, thus preventing any poor surface condition of shaft or coupling from contributing to poor measurements.
5. Support the dial indicator weight on the motor or pump shaft so it does not contribute to "reach bar" sag.
6. Do not overlook the fact that many times one can clamp to the shaft behind each coupling hub and obtain more span and therefore better accuracy.
7. Record all data looking the *same* way down the unit; that is, top east, bottom, west or top, north bottom, south or top, right bottom, left. It is suggested that the driver-pump always be viewed from the driver end.
8. Turn the shafts in the direction they normally turn and approach the 90° points in a precise manner (do not back up and introduce backlash errors). Turning in the normal direction is good training because, on gear units, it reduces helix angle lift errors.

Indicator bar sag can be determined by firmly affixing it to a sag-free shaft mandrel, usually 4-in (10-cm) diameter or larger, dependent on length. The mandrel may be supported between lathe centers, mounted on knife edges, or held and rotated by hand. With the indicator bar positioned on top of the mandrel, the sag of the bar will be down toward the mandrel. Set indicator face to read zero at this position. By zeroing the indicator, you have erred the indicator by the amount of the sag. Rotate the mandrel 180° (indicator at bottom position). The indicator bar will sag away from the mandrel; hence the indicator reading will be twice the actual bar sag and will read negative as shown in (a).

$$\left(\frac{\text{TIR}}{2} = \text{Sag} \right)$$

FIGURE 19A through D Illustrative procedure to determine the amount of sag in an indicator bar (bracket) (Courtesy Reference 3)

9. If the motor can be turned down from the end opposite the end from which the measurements are taken, do so. Regardless, always release the strap wrench or spanner bar before recording each $\frac{1}{4}$ -point reading.
10. Obtain center zero dial indicators or revolution counter indicators or carefully note all indicator movements with a mirror to assure, for example, that 0.090 in was not really -0.010 in. The algebraic sum of horizontal and vertical readings should be near equal.

INSTRUMENTS FOR VIBRATION ANALYSIS

One fact about end-suction and between-bearing pumps is that external visual evidence of mechanical problems is very limited. Only three gauges for mechanical trouble exist: temperature, vibration, and sound.

FIGURE 20 Complex vibration signal resolves into sine wave spectrum

It is normal for a machine to vibrate at some level; such vibrations are caused by manufacturing defects, design limits of the pump, casting irregularities, less than optimum application, and a maintenance/installation problem. When the velocity vibration level starts to increase 0.1 in/s (2.5 mm/s) zero to peak (0-P) above the "as new installed level," the vibration should be analyzed to determine the possible sources of the mechanical and/or hydraulic problem. Several mechanical and/or hydraulic problems may be producing, for instance, the $1\times$ running speed frequency vibration. The key in using vibration to define the mechanical and/or hydraulic problems is to determine the *frequency* at which the vibration occurs. Vibration *amplitude* is also an important factor because it indicates the severity of the vibration. Field vibration data are normally a complex vibration waveform. By using a tunable analyzer, the complex vibration signal, as shown in Figure 20, can be filtered or tuned into its basic frequency components; that is, all complex signals are summations of the harmonics and subharmonics $1\times$, $0.5\times$, $6\times$, $30\times$, and so on. By comparing these filtered components of the complexed vibration signal with an analysis chart and some common-sense experience, probable causes of the vibration can be listed.

The first step toward resolving the vibration problem is to convert the mechanical movement to an equivalent electrical signal so it can be filtered and measured.

Often used analyzer systems are

1. A turbine ac-battery-powered analyzer with strobe light, providing amplitude, frequency, and phase. A plotter accessory can also be attached for copies of the data.
2. A small battery-powered, internally driven, tunable analyzer with a built-in plotter using an accelerometer or velocity sensor.
3. A spectrum analyzer, ac powered, that receives the signal directly from a vibration transducer or the recorded signal from a battery-powered four-channel FM/AM cassette tape recorder.

For startup or where the problem is tougher, one can add

1. Eight-channel FM tape recorder
2. Four-channel oscilloscope with blanking and time display
3. Tracking filter displaying revolutions per minute, amplitude, and phase, capable of tracking runup/run-down data

FIGURE 21 Limitations on machinery vibration analysis systems and transducers (mils \times 0.0254 = mm; in/s \times 25.4 = mm/s) (Reference 10)

Provisions should be made for the use of all types of sensors, as there are advantages in each. As more complex problems continue to appear, tunable analyzers with a sensor are not just a requirement but a necessity in any maintenance reliability program. The choice of a displacement sensor (eddy current probe), velocity or seismic sensor, or an accelerometer depends on the frequency range to be analyzed and the type of pumping equipment. There is no one vibration sensor for all jobs.

Of the three types of vibration measurements, acceleration and displacement are dependent on frequency and velocity is independent of frequency. Most engineers and technicians select a measurement that is independent of frequency for a datum to judge the general health of new and used pumps. With the exception of low-speed pumps and motors, 1750 rpm or less, unfiltered velocity and filtered velocity are used for most basic data. Figure 21 shows the frequency relationships (log) versus output (log) of three different measurement sensors with reference to a constant velocity of 0.3 in/s (7.6 mm/s). The figure gives an overview of present sensor limits and shows that each sensor is like a window through which portions of the frequency spectrum may be observed. The figure also shows that the accelerometer is the choice sensor at high frequency because it measures the square of the frequency. The advantage of displacement at low frequencies is due to its high output; the disadvantage of displacement at high frequencies is that the output signal will disappear into the background noise of most measuring systems.

One should not confuse the measurement parameters (displacement, velocity, and acceleration) with the sensors (eddy current probes for displacement, velocity sensors, and accelerometers). The basic relationship of these measurement parameters with commonly used units are shown on a simple sine wave in Figure 22.

Although the velocity sensor is not necessarily the *best* all-around type of sensor, it does have the advantage of high self-generating output (up to 1000 ft [300 m] of cable), can be mounted in any position, and is influenced only slightly (less than 5%) by transverse sensitivity (side forces). The disadvantages are that the output signal below 600 cpm is significantly nonlinear but can be corrected, the accuracy is limited at $\pm 8\%$ to 1000 Hz, and

FIGURE 22 Basic relationship of measured parameters with a simple sinusoidal vibration

the sensor will most likely have problems in one to two years when mounted in field applications where vibration is high, especially vane passing frequencies.

The piezoelectric accelerometer is a very light and compact sensor that measures vibration using a mass mounted on a piezoelectric crystal. Its output is low and requires a charge amplifier in the lead even with very short leads. The accelerometer is small and can be mounted virtually anywhere; it has a 1 to 3% influence factor from transverse side forces. A good rule of thumb on the usable frequency range is one-fifth to one-third of the resonant frequency. The disadvantages are that the sensor is sensitive to mounting torque, although stud mount is the best method to mount accelerometers. A lot of data are produced, of which some may be the data from an excited accelerometer resonance or cable noise. An impedance matching device can be built into the accelerometer for use at temperatures below 250°F (120°C), and cable noise can be greatly reduced with the voltage and charge sensitivity greatly improved; for example, 100 mV/g and 50 to 100 pC/g (where g = number of accelerations of gravity). For higher temperatures, the accelerometer will need a separate charge amplifier and may need heat insulation, such as MICA wafers (refer to API 678, dated 1981).

Most so-called ultrasonic analyzers use the accelerometer as a structural microphone. Many have chosen a carrier frequency in the megahertz range to improve the signal-to-noise ratio and make characteristic high-frequency patterns. Most of these systems are still in the development stage.

Techniques for Taking Data The second most important part of a vibration analysis program is the type of data taken and the techniques used to take the data. The purpose of taking vibration data on a pump is to either perform an analysis because someone noticed a noise or increased vibration level, or as a part of a periodic preventative maintenance program. It has been proven from experience that the velocity measurement is the best method for determining acceptable levels of centrifugal pump vibration. This is not to say that displacement and acceleration are not measures of vibration severity; they are, but it is necessary to know the frequency of the vibration. Displacement is preferred by a few for frequencies less than 6000 cpm. Accelerometers matched with analyzers can be purchased with signal integration that will give reliable readings in velocity in the 3000- to 60,000-cpm range. For readings above 60,000 cpm, the sensor would generally be an accelerometer reading in g 's, peak or integrated to read velocity zero to peak or 0-P.

Vibration amplitude is an important parameter because it indicates the approximate severity of the dynamic stress levels in the pump. Experience has shown that the shaft

bearings and seal will probably fail in a pump with a velocity reading of 0.5 in/s (13 mm/s) 0-P. Also, catastrophic failures will probably occur when a pump is at 1 in/s (2.5 mm/s) 0-P. Pumps with velocity readings of 0.05 to 0.15 in/s (1.3 to 3.8 mm/s) 0-P, will perform well mechanically. Vibration readings are taken in the horizontal and vertical planes on the bearing housing of horizontal-shaft pumps.

To have a worthwhile maintenance reliability program with pumps, vibration readings must be recorded regularly (that is, monthly). This can range from a trend plotting of unfiltered vibration to a full vibration analysis using a real-time analyzer to generate the frequency spectrum. A standard method used by many companies consists of taping pump vibrations with a battery-powered cassette recorder using a velocity sensor. Readings can then be processed through a real-time analyzer and recorded on an *XYZ* plotter. The best application of this method is during startup and repair evaluation.

As an alternate method, a spectrum analyzer/plotter that produces a spectrum on a 4 in \times 6 in (10 mm \times 15 mm) card with a frequency plot versus amplitude can be used. This procedure has in some installations detected and corrected 95% of the mechanical problems before failure. Experience has shown that had unfiltered displacement readings been taken, only 60 to 70% of the mechanical problems would have been observed. During these recordings, emphasis should be placed on the change in vibration levels, which is a better indication of a mechanical problem than absolute vibration.

One of the best pieces of data available for the pump's equipment file is a vibration record taken during the manufacturer's test or during water batching or commissioning. It is advisable to request a witness performance test on key or critical pumps. The purpose of this test is to assure mechanical reliability *along with* performance.

The manufacturer should be asked about the availability and type of vibration analysis equipment and sensors. Regardless of the instruments used, the vibration data sheet for the tested pump should have a sketch of where all vibration points were taken. The manufacturer should also supply a complete mechanical description of the number of impeller vanes, number of casing volute cutwaters or diffuser vanes, type of coupling, length of coupling spacer, and so on.

There are several different methods for taking periodic vibration data on pumps:

1. Using a handheld battery-powered velocity probe/readout, a machinist or operator logs unfiltered readings taken at one or two points on the bearing housing. When the reading reaches 0.3 to 0.5 in/s (8 to 13 mm/s) 0-P, the pump is pulled for maintenance. Readings are usually taken every two weeks.
2. Vibration points in the vertical, horizontal, and axial directions are recorded on a tabulated chart in unfiltered and filtered velocity at the various peak amplitudes, using a battery-powered tunable analyzer with a velocity sensor.
3. Vibrations in the vertical, horizontal, and axial direction are taken at each bearing, using a velocity sensor. The signal is recorded on a tape recorder, preferably a battery-powered FM/AM cassette. These data are then processed through a real-time analyzer. A spectrum hard copy is made on an *XYZ* plotter of velocity versus frequency.
4. Key vibration points are fed directly from a velocity sensor or an accelerometer/charge amplifier through a long extension cable to a safe area, where a real-time analyzer processes the signal into a velocity versus frequency spectrum or a *g*'s (acceleration) versus frequency spectrum. Hard copies for records are made on a *XYZ* plotter. This method requires two technicians with radios.

The most accurate are methods 3 and 4. The most costly to run in workerhours per point is method 2. The least accurate is, of course, method 1, but it is a popular screening technique.

Use of Vibration Sensors The use of a handheld velocity sensor with an aluminum extension rod or a light-duty vise grip with the probe mounted on the top of the grip has produced some high and misleading vibration readings because of extension resonances. For instance, the vise grip should not be used because of a 5000-cpm resonance. A 9-in (23 cm) long by $\frac{5}{8}$ -in (0.95-cm) diameter extension to the velocity pickup should not be used above 16,000 cpm. The approximate axial natural frequency in cycles per minute for a rod extension from the probe, in tension and compression, can be expressed as

in USCS units
$$f_n = 188 \sqrt{\frac{AE}{WL}}$$

in SI units
$$f_n = 946 \sqrt{\frac{AE}{WL}}$$

where W = pickup weight (force), lb (N)

L = length of rod, in (m)

A = cross-sectional area of rod, in² (m²)

E = modulus of elasticity of rod, ° lb/in² (kPa)

Use of attachments above these listed frequencies will produce a higher amplitude.

The best and simplest method of holding a velocity probe to a pump is a two-bar magnetic holder on the end of a velocity probe. Proper cleaning and some paint removal are generally necessary for good attachment. Periodic wiping of the magnetic bar to remove iron filings is also necessary. After mounting the probe, give it a light twist and a rocking motion; if it twists easily or rocks, change locations or reclean the surface. This location should be marked and future readings taken on the same spot; otherwise, the trend plots will vary.

If there is a concern about an extension or magnetic holder resonance, test this by holding the sensor, without the extension or magnetic holder, directly to a reasonably flat spot and noting any differences. Holding the sensor on a flat spot is generally safe up to 60,000 cpm.

When measuring vibration on an electric motor, there is always the possibility of false readings at 60 and/or 120 Hz due to electrical induction by the motor. This can be checked by two methods:

1. Hold the sensor by its cord and move it toward the motor, noting any increase in amplitude.
2. Using a two-channel oscilloscope, trigger the filtered signal against line voltage. In-phase signals mean the vibration is electrically induced.

For field use, one usually does not have to contend with temperatures above 250°F (120°C) direct to the sensor; thus, accelerometers with built-in impedance matching devices can be used and 100 mV/g voltage sensitivities can be obtained and transmitted 300 ft (90 m) if necessary. If the frequency range is low, and it is for pumps, a charge sensitivity in the order of 100 pC/g can also be obtained.

Techniques for Taking Preliminary Vibration Readings Some key points to remember before you start your analysis of the vibration problem:

1. Do not reach a decision on what the problem is before you record and analyze the data. By deciding too quickly what the problem is, you will most likely neglect other important factors.
2. Before you take the data, take time to review maintenance logs, talk with the area mechanic and operator, and make notes on the following:
 - a. Are there any unusual sounds (cavitation, bearings, and so on)?
 - b. Is there any movement in the discharge pressure gage?
 - c. What is the direction of rotation?
 - d. Are the flush and cooling lines lined up properly?
 - e. Is there any movement in the coupling shim pack?
 - f. Are there any foundation cracks?
 - g. Are pipe supports functioning properly?
 - h. Has a suction screen been installed?

°For aluminum, $E = 10.3 \times 10^6$ lb/in² (71×10^6 kPa). For steel, $E = 30 \times 10^6$ lb/in² (207×10^6 kPa)

- i. What is the magnitude of the liquid velocity in the suction line?
- j. Is the automatic oiler level adjusted correctly?
- k. Where is the pump being operated?
 - l. What are the flow, suction, and discharge pressure?
- m. Is the pump's minimum flow bypass system in service?
- n. Has the process changed?
- o. What is the suction valve stem orientation?
- p. Have there been any color changes in the paint?
- q. Are there any loose parts, including the coupling guard?
- r. Determine the color and feel of the oil (if possible).
- s. What is the bearing housing temperature?
- t. How is the coupling guard attached (attachment to the bearing housing is poor practice)?

You will be surprised how much this information aids in an analysis. Example: you record a high 1× in the radial plane, low values of 2× and 5×, and several high-frequency components at about 0.15 in/s (4 mm/s) O-P. The 1× could be a bent shaft, loose coupling, plugged impeller, bad coupling unbalance, upper and lower case halves misaligned, and a whole list of running frequencies symptoms. During your review of maintenance logs, you noted that the impeller had been replaced because there had been distillation column tray part damage. The next questions you should ask are, "Did maintenance reinstall the suction screen?" (if not, another tray part may have lodged in the impeller) and, "Was the impeller rebalanced after it was trimmed from maximum diameter?"

- 3. Do not try to interpret partial vibration readings for someone looking over your shoulder before you have even taken all the readings. Sit down in a quiet place with your notes on installation and maintenance, a symptoms list, and a severity chart and then make the analysis. Analysis is not a simple task, but with some experience you will build confidence and it will become second nature.

VIBRATION DIAGNOSTICS

Analysis Symptoms The vibration severity chart and vibration identification chart are guides, but experience, a set of procedures, and study of the literature will make diagnostics easier. To be effective, one must be thoroughly familiar with the machinery's internal construction, installation, and basic control system. Both mechanical and hydraulic mechanisms can produce symptoms of vibration.

The vibration analysis symptoms, or vibration severity criteria, chart has taken on many forms since the Rathbone chart of 1939. Perhaps the most widely used symptoms chart in the turbo-machinery field today is the original paper published by Sohre.⁵ A condensation and revision of the original paper is shown in Table 2. Although this chart includes some symptoms that will never appear in pumps, it is one of the better references for vibration analysis. The way the table gives percentages of cases showing the symptoms for the causes listed is unique. As one learns to use the chart and modifies it with experience, a good diagnostic tool will be developed.

A good guide for unfiltered bearing cap velocity limits on field installed pumps is given in Table 3. A guide for shop testing new and rebuilt pumps is given in Reference 6.

Comments on Table 2 In the following comments, the numbers correspond to "Cause of vibration" in Table 2.

- 1. Long, high-speed rotors often require field balancing at full speed to make adjustments for rotor deflection and final support conditions. Corrections can be made at balancing rings or at coupling bolts.

TABLE 2 Vibration analysis symptoms

| Cause of vibration | Predominant frequencies | | | | | | | | | | | Vert. | Hor. |
|---|--|--------|---------|----------------------|----------------------|------------------|---------------------|---------------------|-----------------|---------------|---------------------|-------|------|
| | 0-40% | 40-50% | 50-100% | 1X running frequency | 2X running frequency | Higher multiples | ½ running frequency | ¼ running frequency | Lower multiples | Odd frequency | Very high frequency | | |
| 1. Initial unbalance | .. | .. | .. | 90 | 5 | 5 | .. | .. | .. | .. | .. | 40 | 50 |
| 2. Permanent bow or lost rotor parts (vanes) | .. | .. | .. | 90 | 5 | 5 | .. | .. | .. | .. | .. | ↓ | ↓ |
| 3. Temporary rotor bow | .. | .. | .. | 90 | 5 | 5 | .. | .. | .. | .. | .. | | |
| 4. Casing distortion { Temporary | 10 | | | 80 | 5 | 5 | .. | .. | .. | .. | .. | | |
| | Permanent | | | 80 | 5 | 5 | .. | .. | .. | .. | .. | | |
| 5. Foundation distortion | .. | 20 | .. | 50 | 20 | .. | .. | .. | .. | 10 | .. | | |
| 6. Seal rub | 10 | 10 | 10 | 20 | 10 | 10 | .. | .. | 10 | 10 | 10 | 30 | 40 |
| 7. Rotor rub, axial | 20 | | | 30 | 10 | 10 | .. | .. | 10 | 10 | 10 | 30 | 40 |
| 8. Misalignment | .. | .. | .. | 40 | 50 | 10 | .. | .. | .. | .. | .. | 20 | 30 |
| 9. Piping forces | .. | .. | .. | 40 | 50 | 10 | .. | .. | .. | .. | .. | 20 | 30 |
| 10. Journal & bearing eccentricity | .. | .. | .. | 80 | 20 | .. | .. | .. | .. | .. | .. | 40 | 50 |
| 11. Bearing damage | 20 | | | 40 | 20 | .. | .. | .. | .. | .. | 20 | 30 | 40 |
| 12. Bearing & support excited vibration (oil whirls, etc.) .. | 10 | 70 | .. | .. | .. | 10 | 10 | .. | .. | .. | .. | 40 | 50 |
| 13. Unequal bearing stiffness horizontal-vertical | .. | .. | .. | .. | 80 | 20 | .. | .. | .. | .. | .. | 40 | 50 |
| 14. Thrust bearing damage | 90 | | | | | .. | .. | .. | .. | .. | 10 | 20 | 30 |
| Insufficient tightness in assembly of: | Predominant frequency will show at lowest critical or resonant frequency | | | | | | | .. | .. | .. | .. | | |
| 15. Rotor (shrink fits) ... | 40 | 40 | 10 | .. | .. | .. | .. | .. | .. | 10 | .. | 40 | 50 |
| 16. Bearing liner | 90 | | | .. | .. | .. | .. | .. | .. | 10 | .. | 40 | 50 |
| 17. Bearing cases | 90 | | | .. | .. | .. | .. | .. | .. | 10 | .. | 40 | 50 |
| 18. Casing & support ... | 50 | | | .. | .. | .. | .. | .. | .. | 50 | .. | 40 | 50 |
| 19. Gear inaccuracy | .. | .. | .. | .. | .. | 20 | .. | .. | .. | 20 | 60 | 30 | 50 |
| 20. Coupling inaccuracy or damage | 10 | 20 | 10 | 20 | 30 | 10 | .. | .. | .. | .. | .. | 30 | 40 |

Numbers indicate percent of cases showing previous symptoms, for causes listed in vertical column at left.

TABLE 3 Bearing cap data-velocity unfiltered

| Smooth | Acceptable | Marginal | Planned shutdown for repairs | Immediate shutdown |
|-----------------------|------------------|------------------|------------------------------------|-----------------------|
| 0.1 in/s (p) and less | 0.1–0.2 in/s (p) | 0.2–0.3 in/s (p) | 0.3–0.5 in/s (p) | 0.5 in/s (p) |

Note: For gearing, add 0.1 in/s to all values.
p = peak
mm/s = 25.4 × in/s

2. Bent rotors can sometimes be straightened by the “hot-spot” procedure, but this should be regarded as a temporary solution because bow will come back in time. Several rotor failures have resulted from this practice. If blades or disks have failed, check for corrosion fatigue, stress corrosion, resonance, off-design operation.
3. Straighten bow slowly, running on turning gear or at low speed. If rubbing occurs, trip unit immediately and keep the rotor turning 90° using a shaft wrench every 5 minutes until the rub clears; resume slow run. This may take 12 to 24 h.
4. Often requires complete rework or new case, but sometimes a mild distortion corrects itself with time (requires periodic internal and external realignment). Usually caused by excessive piping forces or thermal shock.
5. Usually caused by poor mat under the foundation or thermal stress (hot spots) or unequal shrinkage. May require extensive and costly repairs.
6. Slight rub may clear, but trip the unit immediately if a high-speed rub gets worse. Turn by hand until clear.
7. Unless thrust bearing has failed, this is caused by rapid changes of load and temperature. Machine should be opened and inspected.
8. Usually caused by excessive pipe strain or inadequate mounting and foundation, but is sometimes caused by local heat from pipes or the sun’s heating the base and foundation.
9. Most trouble is caused by poor pipe supports (should use spring hangers), improperly used expansion joints, and poor pipe line up at casing connections. Foundation setting can also cause severe strain.
10. Bearings may become distorted from heat. Make a hot check, if possible, observing contact.
11. Watch for brown discoloration, which often precedes recurring failures. This indicates very high local oil film temperatures. Check rotor for vibration. Check bearing design and hot clearances. Check condition of oil, especially viscosity.
12. Check clearances and roundness of journal, as well as contact and tight bearing fit in the case. Watch out for vibration transmission from other sources and check the frequency. May require antiwhirl bearings or tilting-shoe bearings. Check especially for resonances at whirl frequency (or multiples) in foundation and piping.
13. This can excite resonances and criticals and combinations thereof at two times running frequency. Usually difficult to field balance because, when horizontal vibration improves, vertical vibration gets worse and vice versa. It may be necessary to increase horizontal bearing support stiffness (or mass) if the problem is severe.
14. Usually the result of slugging the machine with fluid, solids built up on rotor, or off-design operation (especially surging).
15. The frequency at rotor support critical is characteristic. Disks and sleeves may have lost their interference fit by rapid temperature changes. Parts usually are not loose at standstill.

16. It is often confused with oil whirl because the characteristics are essentially the same. Before suspecting any whirl, make sure everything in the bearing assembly is absolutely tight with an interference fit.
17. This should always be checked.
18. It usually involves shading pedestals and casing feet. Check for friction, proper clearance, and piping strains.
19. To obtain frequencies, tape a microphone to the gear case and record noise on magnetic tape.
20. Loose coupling sleeves are notorious troublemakers, especially in conjunction with long, heavy spacers. Check tooth fit by placing indicators on top, then lifting by hand or a jack and noting looseness (should not be more than 1–2 mils [0.025 to 0.05 mm] at standstill, at most). Use hollow coupling spacers. Make sure coupling hubs have at least 1 mil/in (1 mm/m) interference fit on shaft. Loose hubs have caused many shaft failures and serious vibration problems.
21. Try field balancing; more viscous oil (colder); larger, longer bearings with minimum clearance and tight fit; stiffen bearing supports and other structures between bearing and ground. This is basically a design problem. It may require additional stabilizing bearings or a solid coupling. It is difficult to correct in the field. With high-speed machines, adding mass at the bearing case helps considerably.
22. These are criticals of the spacer-teeth-overhang subsystem. Often encountered with long spacers. Make sure of tight-fitting teeth with a slight interference at standstill and make the spacer as light and stiff as possible (tubular). Consider using a solid or membrane coupling if the problem is severe. Check coupling balance.
23. Overhang criticals can be exceedingly troublesome. Long overhangs shift the nodal point of the rotor deflection line (free-free mode) toward the bearing, robbing the bearing of its damping capability. This can make critical speeds so rough it is impossible to pass through these speeds. Shorten the overhang or put in an outboard bearing for stabilization.
24. Casing resonance is also called case drumming. It can be very persistent but is sometimes harmless. The danger is that parts may come loose and fall into the machine. Also, rotor/casing interaction may be involved. Diaphragm drumming is serious because it can cause catastrophic failure of the diaphragm.
25. Local drumming is usually harmless, but major resonances, resulting in vibration of the entire case as a unit, are potentially dangerous because of possible rubs and component failures, as well as possible excitation of other vibrations.
26. Similar problems exist as in 24 and 25 with the added complications of settling, cracking, warping, and misalignment. This cause may also produce piping troubles and possible case warpage. Foundation resonance is serious and greatly reduces unit reliability.
27. Pressure pulsations can excite other vibrations with possible serious consequences. Eliminate such vibrations using restraints, flexible pipe supports, sway braces, shock absorbers, and so on, plus isolation of the foundation from piping, building, basement, and operating floor.
28. It occurs mostly at two times line frequency (7200 cpm), coming from motor and generator fields. Turn the fields off to verify the source. It is usually harmless, but if the foundation or other components (rotor critical or torsional) are resonant, the vibrations may be severe. There is a risk of catastrophic failure if there is a short circuit or other upsets.
29. This can excite serious vibrations or cause bearing failures. Isolate the piping and foundation and use shock absorbers and sway braces.
30. Valve vibration is rare but sometimes very violent. Such vibrations are aerodynamically excited. Change the valve shape to reduce turbulence and increase rigidity in the valve gear. Make sure the valve cannot spin.
31. The vibration is exactly one-half, one-quarter, one-eighth of the exciting frequency. It can be excited only in nonlinear systems; therefore, look for such things as looseness

and aerodynamic or hydrodynamic excitations. It may involve rotor “shuttling.” If so, check the seal system, thrust clearances, couplings, and rotor-stator clearance effects.

32. The vibrations are at two, three, and four times exciting frequency. The treatment is the same as for direct resonance: change the frequency and add damping.
33. If the cause is intermittent, look into temperature variations. Usually the rotor must be rebuilt, but first try to increase stator damping, add larger bearings (tilting-shoe), increase stator mass and stiffness, and improve the foundation. This problem is usually caused by maloperation, such as quick temperature changes and fluid slugging. Use membrane-type coupling.
34. This is basically a design problem, but is often aggravated by poor balancing and a poor foundation. Try to field-balance the rotor at operating speed, lower oil temperature, and use larger and tighter bearings.
35. Add mass or change stiffness to shift the resonant frequency. Add damping. Reduce excitation and improve system isolation. Reducing mass or stiffness can leave the amplitude the same even if resonant frequency shifts because of stronger amplification. Check “mobility.”
36. Stiffen the foundation or bearing structure. Add mass at the bearing, increase critical speed, or use tilting-shoe bearings (which is the best solution). First, check for loose fit of bearings in bearing case.
37. Same comments as 36 with additional resonance of rotor, stator, foundation, piping, or external excitation; find the resonant members and the sources of excitation. Tilting-shoe bearings are the best. Check for loose bearings.
38. Sometimes you can hear the squeal of a bearing or seal, but frequency is usually ultrasonic—very destructive. Check for rotor vanes hitting the stator, especially if clearances are smaller than the oil film thickness plus rotor deflection while passing through the critical speed.
39. Usually accompanied by rocking motions and beating within clearances. It is serious especially in the bearing assembly. Frequencies are often below running frequency. Make sure everything is absolutely tight, with some interference. Line-in-line fits are usually not sufficient to positively prevent this type of problem.
40. This problem is very destructive and difficult to find. The symptoms are gear noise, wear on the hack side of teeth, strong electrical noise or vibration, loose coupling bolts, and fretting corrosion under the coupling bolts. There is wear on both sides of coupling teeth and possibly torsional-fatigue cracks in keyway ends. The best solution is to install properly tuned torsional vibration dampers.
41. It is similar to 40, but encountered only during startup and shutdown because of very strong torsional pulsations. It occurs in reciprocating machinery and synchronous motors. Check for torsional cracks.

Impeller Unbalance Impeller unbalance appears as a $1\times$ running speed frequency vibration approximately 90% of the time and may be mechanical or hydraulic in origin. Impeller mechanical unbalance is a frequent cause of mechanical seal and bearing failures. Many mechanics will never think of checking impeller balance until heavily pitted areas appear. Because of the nonhomogeneous nature of most castings, corrosion is usually more aggressive in one area of the impeller. The degree of etching or surface pitting is a judgmental indicator of balance change. Impeller balancing should be part of the shop repair procedure for impellers over 10 in (25 cm) at 3600 rpm. It is good practice, when balancing an impeller, to keep the impeller bore to balance mandrel fit no greater than 0.001 in (0.0254 mm) loose. Installing the impeller with the keyway up on the balance mandrel and pump shaft will help eliminate some of the unbalance due to shaft center-line shift.

EXAMPLE A 38-lb (17.2 kg), 15 $\frac{1}{2}$ -in (39.4-cm) diameter impeller operating at 3600 rpm is balanced on a machine good to 25×10^{-6} in (635×10^{-6} mm) using an expanding man-

drel. The impeller is then installed on its shaft, which has a loose fit of 0.0035 in (0.0889 mm). The forces created by this shift in the center of mass is calculated as follows:

in USCS units

$$\begin{aligned}\text{Unbalance} &= \text{eccentricity of impeller (in)} \times \text{impeller wt. force (oz)} \\ &= \frac{0.0035}{2} \times 38 \times 16 = 1.064 \text{ oz} \cdot \text{in} \\ \text{Unbalance force} &= 1.77 \left(\frac{\text{rpm}}{1000} \right)^2 \times \text{unbalance (oz} \cdot \text{in)} \\ &= 1.77 \left(\frac{3600}{1000} \right)^2 \times 1.064 = 24.4 \text{ lb}\end{aligned}$$

in SI units

$$\begin{aligned}\text{Unbalance} &= \text{eccentricity of impeller (mm)} \times \text{impeller wt. mass (g)} \\ &= \frac{0.0889}{2} \times 17.2 \times 1000 = 765 \text{ g} \cdot \text{mm} \\ \text{Unbalance force} &= 0.01094 \left(\frac{\text{rpm}}{1000} \right)^2 \times \text{unbalance (g} \cdot \text{mm)} \\ &= 0.01094 \left(\frac{3600}{1000} \right)^2 \times 765 = 108.5 \text{ N}\end{aligned}$$

The example also points out that the unbalance force generated by loose fit impellers with keyways mounted in one plane could be quite high. This force could be minimized by staggering keyways or randomly orienting the impellers on the balance mandrel. Shifting of shrink-fitted, well-balanced impellers on multistage and high-speed double-suction pumps after a period of operation can result in unbalance. The shifting of the impeller is due to the relaxation of residual stresses that built up as the impeller cooled and contracted around the shaft. Shaft vibration and flexing tend to relieve the residual stress and cause the impeller to cock or bow the shaft from the original balance centerline.

Standards should be referred to for balancing pumps and their drivers. When balancing, consideration must be given to the need for balancing at rated speed in order to properly evaluate the importance of shaft deflection due to modal components of unbalance. See References 12 and 13.

Hydraulic Unbalance Uneven flow distribution entering the impeller can cause a $1\times$ running speed frequency type of vibration. The unbalance occurs because the flow is not equal in all vane passages. An example of this is a double-suction impeller with a short, straight run to the pump and an elbow in the horizontal plane. Flow from the elbow does not have time to straighten and therefore enters both sides of the impeller unequally. A similar condition results if suction is taken from a tee off the main header. Unequal and unsteady flow into the impeller may cause axial thrust and high axial vibrations. Thus, it is good design practice to install elbows vertically in double-suction pumps.

In double-suction pumps, the nonsymmetrical positioning of the impeller or the offset of the upper case half of the lower case half will cause a $1\times$ unbalance due to nonsymmetrical flow.

Recirculation forces and pulsation recirculation within a pump (which can occur when flow is less than design) may manifest themselves in the form of a noise and/or vibration with random frequencies, along with pressure pulsation that may be seen on a pressure gage. Recirculation may also appear in the piping system as vibration and noise. Increased *NPSHA* has helped in a few cases, especially if the recirculation is mainly on the suction side of the impeller. After a pump has a recirculation problem in a given system and the

flow cannot be increased using a bypass, little can be done to the pump itself unless the system characteristics allow an impeller change.

Antifriction Bearings Vibrations generated by ball bearings cover a wide range of high frequencies that are not necessarily a multiple of the shaft running speed. The frequency readings obtained during analysis are somewhat unsteady because of the resolution of the filters in a hand-tuned analyzer. The amplitude reading may also be somewhat unsteady.

Experience has shown that hand-tuned field analyzers tend to show the last stage of the bearing failure. Monitoring of stress waves or shock pulses (impact energy) on the pump bearing housing will show failure trends that will generally precede an increase in the detectable level of mechanical vibration. This method of failure detection is called acoustic high-frequency monitoring or incipient-failure detection (IFD). A comparison between conventional methods and the acoustic high-frequency method is shown in Figure 23.

Accurate analysis of pump bearings and other machinery can also be made using a velocity sensor good to 1500 Hz or an accelerometer. Data should be recorded and processed through a real-time analyzer with at least 256-line resolution capability and a band selectable analysis option. Analysis of antifriction bearings using a real-time analyzer and equations for calculating frequencies generated by defective bearings can be found in Reference 7.

Accurate and extended analysis of pump bearing vibration is generally not needed. A majority of bearing problems are currently identified by an acoustic noise during operation. What is needed by maintenance personnel is a quick and reliable method to monitor bearings and determine when a bearing is failing and the rate of bearing deterioration. At present, there are some expensive instruments that can be purchased, but none of them meet maintenance requirements.

Currently, the best method for reducing bearings analysis is prevention of the failure. Most antifriction pump bearings fail for one of several reasons: (1) water gets into the oil, (2) automatic oiler is not adjusted properly (this cause is most often overlooked and will continue to produce a short life to failure cycle), (3) product gets into the oil, (4) acidic vapors condense and break down the oil, (5) mounting techniques or fits are improper, (6) new bearing is defective. The solution to high-humidity problems and problems with acidic units is the use of an oil mist lubrication system. If this cannot be economically installed, an aggressive preventative maintenance program on a monthly to every-other-month basis is required.

FIGURE 23 Relative signal strength versus days to failure for acoustic IFD and conventional vibration monitoring methods

Baseplates With the change from low rotating speeds and cast iron baseplates to the less rigid fabricated steel baseplates and higher rotating speeds, higher operating temperatures, and larger impellers have greatly increased the probability of baseplate vibrations, distortion, and a decreased stiffness for rotor dynamics. Reference 6 has increased coverage for piping loads and the option of a heavy-duty baseplate over the proposed standard baseplate. The reference specifies a standard baseplate and pedestal support that are twice as rigid as specified in the fifth edition of the reference standards.

Baseplate vibration problems can be resolved at the design stage or during construction. Engineering specifications should call for leveling screws, grout filling holes [4 in (10 cm) minimum, 6 in (15 cm) preferred for each bulkhead section], venting holes [$4\frac{1}{2}$ in (11 cm) holes to each bulkhead section], and corrosion protection. A check of the outline dimension approval drawing should also be made for proper grout hole placement (bulkhead and cross bracing must be shown on the drawing). Construction specifications should call for proper baseplate preparation before grouting.⁸ API pumps should have epoxy grout bonding the baseplate to the concrete foundation.

After proper cure, the baseplate should be tapped for voids, especially between and under the pump centerline supports.

EXAMPLE A high vertical vibration occurred on the coupling end bearing at vane passing frequency on a multistage volute pump. The vertical vibration was 2.5 times the horizontal; thus, a check of the bearing pedestal and baseplate was in order. The hammer test on the pan of the baseplate under the bearing pedestal showed complete lack of grout. Vertical vibration on the pan was 1.8 times the horizontal. Regrouting eliminated the pan vibration and reduced the vertical vibration to one-half of the horizontal. Lack of proper stiffness from the baseplate can and will lower some pump critical speeds into the operating range.

When a complete analysis is being done on a problem pump, take several pedestal readings (top, middle, and bottom on the side and end) and several readings on the pan of the baseplate. The middle, bottom, and pan readings should show good attenuation.

CENTRIFUGAL PUMP MINIMUM FLOW CONTROL SYSTEMS

HORACE J. MAXWELL
DAVID A. KALIX

In designing centrifugal pumps, engineers strive to develop specific internal geometry that will produce head and flow with low energy loss. Each pump is designed for a specific head versus flowrate for the given impeller speed. The head and flowrate on this family of “characteristic” curves where the energy loss is minimum is known as the Best Efficiency Point (BEP).

In application, pumps spend a significant portion, if not all of their life, operating at conditions other than BEP. This is normal and is due to a combination of system design conditions (for example, static head, piping and valve impedances, and so on), available pump designs (that is, capacities and heads) and actual plant operating requirements. Low flow related problems occur when pumps continuously operate in or repetitively cycle into flow regions that are significantly below the BEP (for example, 50% of BEP). In these low-flow regions, pump and system component performance and longevity can be adversely affected.

Low flow problems are known to be worst for large high-energy pumps (for example, boiler feedwater), for pumps handling hot liquids, for pumps that handle liquids that have solid particles, and for pumps for low net positive suction head (*NPSH*) service. A well-designed minimum flow control system can establish an environment that will substantially improve pump and system performance. The following chapter will briefly review the topics that should be considered when designing a minimum flow system for a centrifugal pump.

FACTORS AFFECTING LOW FLOW RATE PUMP OPERATION_____

Collectively, the following broadly classed factors have been recognized as the major contributors to low flow pump problems.

Thermal Factors The increase in temperature of the liquid within the pump is directly related to the pump's efficiency. The energy that is available to heat the flowing liquid and the pump casing is basically the difference between the power input to the pump (brake horsepower) and the useful work done by the pump (liquid horsepower). At low flow conditions, centrifugal pumps are very inefficient and a significant amount of input energy is lost and heats the liquid and the pump assembly. Refer to Subsection 2.3.1 and Chapter 12 for more discussion on thermal effects.

Hydraulic Instabilities When the pump is operating significantly below the BEP, flow streamlines (that is, patterns) within the pump change considerably from the rated design streamlines. Fluid eddies are most likely to develop at the inlet and discharge of the impeller resulting in flashing, cavitation, and shock waves that often produce vibration and serious component erosion. This phenomenon is classically known as internal recirculation. It can occur at the pump inlet (suction) and discharge. Refer to Subsection 2.3.1 and 2.3.2 for a more in-depth discussion on this topic.

Mechanical Loads As the flowrate through the pump decreases, steady state loads increase and superimposed dynamic cyclic loads appear radially and axially on the impeller and shaft. The dynamic cyclic component increases significantly when recirculation within the pump occurs. Bearing damage, shaft and impeller breakage, and rubbing wear on casing, impeller and wear rings can occur. See Subsections 2.3.2 and 2.3.3 for discussion of this subject.

Axial-flow and mixed-flow pumps with high specific speed produce comparatively higher head and take comparatively more power at low flow. A bypass system may be necessary not only to reduce component loading and stress but also to prevent motor overload. See Subsection 2.3.1 and Section 8.1 for discussion.

Abrasive Fluids Liquids containing a large amount of abrasive particles, such as sand or ash, must flow continuously through the pump. If flow decreases, the particles can circulate inside the pump passages and quickly erode the impeller casing, wear rings, and shaft.

ESTABLISHING MINIMUM PUMP FLOW REQUIREMENTS

The bypass system designer must know the minimum pump flow specified by the pump manufacturer in order to properly design a bypass system. The four previously discussed topics should be evaluated in detail by the pump manufacturer to establish the minimum flowrate specification. Minimum flowrate specifications are generally established through a combination of analytical and experimental techniques coupled with field performance data.

Thermal Considerations The maximum allowable temperature rise of the pump is primarily based on two points: the permissible pump casing and shaft thermal growth and the flash point temperature of the pumpage. Pump manufacturers use analytical, laboratory and field data to validate their thermal analysis to ensure that pumps do not seize within the allowable temperature operating ranges. Refer to Subsection 2.3.1 for temperature rise calculations.

Applications involving extremely high or low temperature fluids may require more in-depth analysis to determine if individual component thermal growth is the limiting factor in determining minimum flowrate. Additionally, certain chemicals, which polymerize or solidify at particular temperatures, may establish the minimum flowrate specification. Chapter 12 and Subsection 2.3.1 provide more detail on this subject.

Hydraulic Considerations The minimum bypass flow requirement for most pumps is based on minimum continuous stable flowrate, a hydraulic criterion, rather than a temperature rise. Pump internal recirculation will occur at both the impeller inlet and

impeller outlet as flowrates are reduced. Internal recirculation will occur at flowrates well above those that cause temperature concerns. Refer to Subsection 2.3.1 for a detailed evaluation of this topic.

Mechanical Considerations It is necessary to know how head, radial thrust, axial thrust and power vary with capacity before deciding on minimum allowable flow. Bearing capacity, motor rating, and stresses in drive and driven components are important influences.

Abrasive Wear Considerations Relatively high bypass flowrates may be required to protect the pump against abrasives in the liquid. Heavy wear can occur at flows below 85% of the best efficiency point. The designer must establish the minimum pump flow specification using the pump manufacturer's recommendation and his experience with comparable pumps and liquid/solid mixtures.

MINIMUM FLOW CONTROL SYSTEM DESIGN FACTORS

Pump Size Capacity, power, specific speed, and suction specific speed are all factors that must be examined when designing a bypass system. These factors have a direct impact on the cost of building and operating the bypass system. Use of a continuous bypass system will require an even larger pump and driver to supply both the process and bypass flow requirements simultaneously.

Discharge Pressure High discharge pressures result in high head loss in bypass valves, components, and lines. Liquids that can flash and cavitate demand special precautions to minimize damage in valving, orifices, and piping.

Available Heat Sink Bypass flow must be reintroduced into the system far enough upstream to prevent progressive temperature buildup or flow disturbance in the pump suction. This may mean a simple discharge back to an uninsulated inlet line or discharge to a receiving tank or cooler with enough area and enough inflow of cool liquid to handle the thermal load. Bypass flow can discharge into a deaerator storage tank, a condenser, a flash tank, or a cooling pond. Elevation, distance, and pressure inside the receiving tank are also factors, as is the fact that the interior must be available for inspection and for repair of spargers, spray or distribution pipes, orifices, and backpressure regulators.

Pump Design A pump's design and materials of construction often affect the minimum allowable percentage of flow. With thermal effects, pumps vary in the length of time that they will tolerate shut off or low flow. This is important in designing the bypass system valves, instrumentation, and controls.

Hydraulic effects at low flow are most apparent in high-energy pumps. The pump manufacturer should state the continuous minimum hydraulically acceptable flow for a given pump—and how it was determined. With axial-flow pumps, the shape of the pump head curve may be a factor in selecting the required bypass flow percentage. If feasible, a witness shop test of the pump should be specified to demonstrate and verify minimum flow recommendations.

Liquid Pumped Liquids that flash and cavitate generally required a high bypass flow percentage. Examples are liquids near the boiling point or at high pressure. Abrasives in the liquid may require more bypass than would be needed for thermal reasons alone.

Energy Costs A high energy cost to operate the pump requires careful consideration of bypass system design. The evaluation should compare equipment installation costs, maintenance, and energy costs for various bypass configurations. Figure 1 shows the annual pumping costs for a continuous bypass type system based on bypass flow, pressure and energy rates. The example shows a pump with a discharge head of 500 ft (152

FIGURE 1 Annual pumping cost estimate for continuous bypass systems (metric conversions: ft $\times 0.3048$ = m, gpm $\times 0.277$ = m³/h, hp $\times 0.746$ = W)

m) and a bypass flow requirement of 400 gpm (91 m³/h). Based on an energy cost of 5.0 cents/KWH, the annual cost for continuous bypass is \$24,000. An automatic bypass system will only open the bypass when process flow demand is low. The total design life energy costs of a continuous bypass system can easily exceed the hardware costs of an automatic bypass system.

Noise Considerations Bypass systems can easily exceed OSHA requirements for occupied spaces if not designed properly. High pressure drops and high fluid velocity increase noise. Multi-stage pressure reduction, heavy wall pipe, insulation, and silencers will all combine to reduce noise to acceptable levels. See Section 8.4 for a further discussion of this topic.

Process System Design and Operational Expectations Bypass system design will depend on the plant design life and the expected process operational requirements. For example, a swing-loaded electric power plant will have far different pump operating requirements than a low-pressure emergency fire water system. The bypass system designer must evaluate installation, maintenance, and operating costs for the life of the process system with the expected utilization. If the actual operating conditions differ significantly from the design, the configuration of the bypass system should be reevaluated. For example, a process designed for normal operation with one pump at 75% of maximum capacity may put severe demands on the bypass system if the pump is operated continuously at 20% of maximum capacity.

LOW FLOW PROTECTION SYSTEMS

Bypass Systems—Types/Design Considerations

CONTINUOUS BYPASS SYSTEMS As the title implies, continuous bypass systems provide continuous flow whenever the pump is running, regardless of the process demand. Figure 2 illustrates a simple system, with a bypass line branching off the pump discharge upstream of the main line check valve and containing a fixed orifice dimensioned by analysis to provide minimum required pump flow. The bypass line discharges into a reservoir that is at a lower pressure than the pump discharge. The bypass line can also discharge directly into the pump supply line. However, the piping system design must ensure that the bypass liquid temperature does not increase to an unacceptable level. Additionally, vapor bubbles formed in the bypass by the pressure reduction process may be introduced into the pump. This will affect pump performance and longevity. Locating the bypass branch-off before the discharge check valve as shown keeps backflow from the process or from a parallel operating pump from going back to the receiving tank or back through the pump during a pump shutdown. Consideration should also be given to installing a check valve in the bypass line.

The size of the bypass pipe depends on flow and piping configuration. If the pressure drop through the orifice results in flashing flow, the orifice should be located at the end of the bypass piping and should discharge directly into the larger receiving tank or larger downstream piping. The discharge flow should be directed so it does not impinge on the walls of the receiving tank but rather into the liquid to absorb the force of cavitation implosion. Valves and fittings located immediately downstream of the orifice may be damaged by cavitation. Full ported gate or ball valves are less susceptible to damage. Waterhammer and erosion are not problems in well-designed continuous bypass systems.

The pump and prime mover must be sized to simultaneously supply both the bypass flow and the maximum process flow at the required pump discharge pressure.

AUTOMATIC BYPASS SYSTEMS Automatic recirculation systems control the bypass flow in relation to the process flow. The sum of the process and bypass flowrates will always exceed the minimum flowrate specified to protect the pump. Two essential elements of these systems are a device to measure the process flow and a device to control the bypass flow. Compared with continuous bypass, these systems reduce energy consumption and pump horsepower requirements.

The bypass flow can be regulated by either “Modulated” or “On-Off” control. When bypass flow is “Modulated,” the bypass flow is inversely proportional to the process flow.

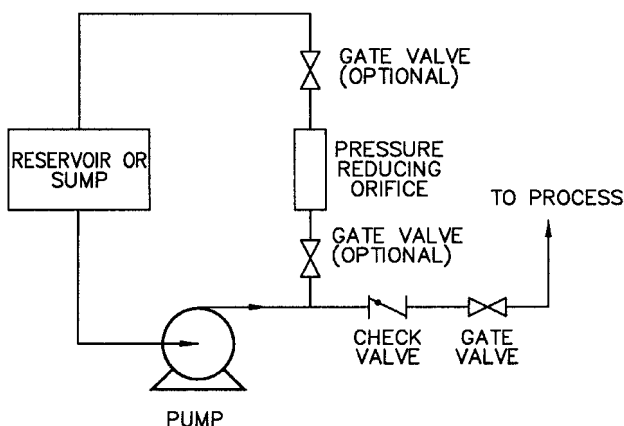

FIGURE 2 Typical continuous bypass system

FIGURE 3 Comparison of On-Off versus Modulated automatic bypass flow control.

The bypass is shut when process flow is greater than the control setpoint (that is, minimum flowrate required), opens more as the process flow is reduced, and is full open when the process flow is zero. With “On-Off” bypass control, the bypass is open fully when process flow is below the setpoint and is shut when the process flow is above the setpoint.

Figure 3 illustrates these control methods and the effect on total pump flow. The total pump flow is the sum of the process and bypass flows; it is the flow that enters the pump suction. The “On-Off” control graph shows that there is a step change in the total flow when the bypass opens or closes. The “Modulated” control regulates the total flow smoothly when the process flow is below the setpoint. Either method will protect the pump from damage due to low flow. However, “On-Off” control may produce large pump discharge pressure variations depending on the shape of pump head curve. Rapid pump flow changes may produce damaging hydraulic or mechanical shocks. This will reduce pump life and increase maintenance. Modulated bypass control is required when the minimum flowrate specification exceeds approximately forty percent of the rated pump capacity. If “On-Off” bypass control is used above this point, the pump may exceed its capacity rating with resultant pressure pulsation and unsteady flow.

CONTROL LOOP SYSTEMS A typical automatic bypass system, based on an instrumented flow control loop, is shown in Figure 4. This system requires a flow meter, a check valve, a bypass control valve, a valve controller and a pressure-reducing orifice.

The flow meter can be placed at the pump inlet or discharge before the bypass tee (as opposed to it having to be placed after the bypass tee in an “On-Off” system). The controller compares the flow meter signal with the setpoint (minimum pump flow required) and operates the bypass control valve.

Single stage control valves are commonly used in low pressure systems with an orifice for pressure reduction located downstream. However, these are not suitable for high pressure differentials or for the controlling of cavitation or flashing. Pressure reducing valves with multi-stage trim, good seat tightness, and low pressure recovery characteristics are widely used in this service. Refer to Chapter 7 for a detailed discussion of control valve characteristics and selection.

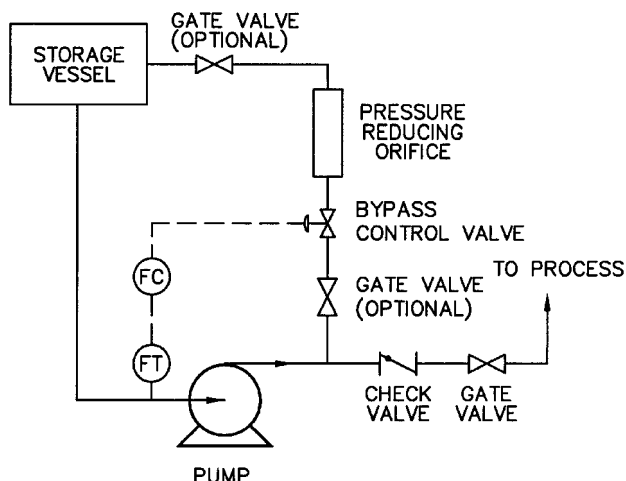

FIGURE 4 Typical automatic bypass system based on flow control

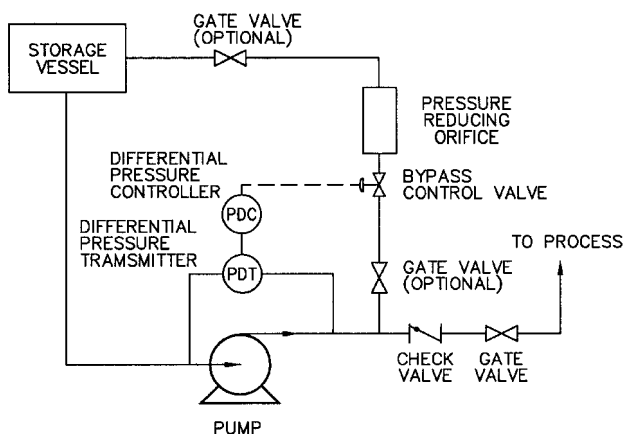

FIGURE 5 Typical automatic bypass system based on pump differential head

The bypass pressure reducing orifice handles the high velocity and erosive forces of the bypass flow. However, the handling of cavitation and flashing by this fixed restriction is limited. The orifice is sized to operate properly at one bypass flow condition. At low flows, the orifice does not provide the correct pressure reduction as designed.

The check valve is placed in the main line, as shown in Figure 4, to prevent reverse flow through the pump. The pump and motor bearings can be damaged if rotated in reverse. Pressure drop through the check valve must be considered in pump sizing in addition to other piping and valve pressure losses.

A typical automatic bypass system based on pump differential head is shown in Figure 5. This system is identical to the flow controlled bypass system except that pump differential head is measured instead of flow. This system can only be used with continuously rising pump head characteristic curves. The system will have to be adjusted for each individual pump characteristic and later adjusted if this characteristic changes over the life of the pump.

Depending on the bypass valve and control instrumentation selected, these systems can provide either “Modulating” or “On-Off” bypass control. Valves, instrumentation, and controls must be individually sized for the service conditions. All components must be integrated together to provide bypass flow control that meets the pump and process operational design criteria.

The Automatic Recirculation Control (ARC®) Valve This valve provides bypass flow control, pressure reduction, and reverse flow pump protection all within a single unit. This single valve combines the functions of the check valve, pressure reducing orifice, pipe tee, control instrumentation flow meter, and bypass control valve that are all required in the instrumented control loop bypass system. Valves can be designed to provide either “Modulated” or “On-Off” bypass control. The operation of all ARC valves is fundamentally the same. The flow sensing element (check valve disc) responds to the process flow demand and opens or closes the self-contained bypass control valve. Differences in ARC valve design center around bypass valve actuation method, repairability, serviceability, and adjustability. Figure 6 illustrates a typical ARC valve bypass system.

Pilotless Trim Design The simplest of ARC valve designs operate the bypass flow control valve directly by the flow sensing element. The construction of a typical ARC for low pressure service is shown in Figure 7. The basic operation of this valve is shown in Figure 8. At zero main flow (“A”), the bypass provides full recirculation flow. As main flow increases (“B”), the bypass modulates proportionally closed. At full main flow (“C”), the bypass is shut. The pressure reduction from the pump discharge to the bypass is accomplished by the characterized orifices in the bypass element that is attached to the disc. However, the differential pressure from inlet to bypass imposes static and dynamic forces on the disc assembly. These unbalanced forces interfere with the normal disc motion and limit the maximum differential pressure for pilotless trim. There is an upper differential pressure limit at which this design will not operate satisfactorily and pilot operated bypass control must be used.

Pilot Operated Trim Pilot operated bypass control valves utilize a combined hydraulic-mechanical force to control the bypass flow. Only a relatively small mechanical force is necessary to hydraulically generate the large forces required to operate a bypass flow control valve in a high-pressure system. Figure 9 illustrates a pilot-operated bypass that utilizes a lever connected to the check valve disc to actuate the pilot. Figure 10 illustrates a pilot operated multistage bypass operated by an in-line pilot valve. Pilot-operated valves require more components and seals than unbalanced valves and are therefore more costly.

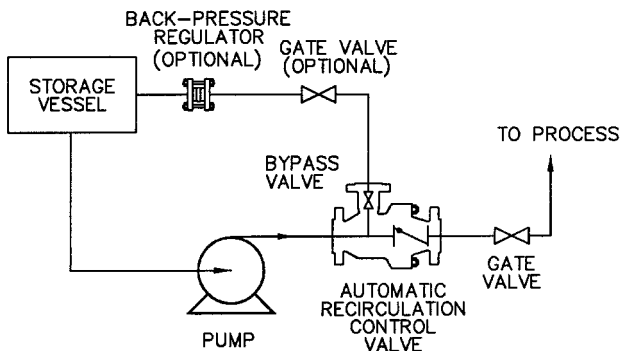

FIGURE 6 Typical ARC valve bypass system

FIGURE 7 Construction of a typical ARC valve for low-pressure service

FIGURE 8A through C Basic ARC valve operation at three process flow conditions

Serviceability ARC valves can be designed for in-line serviceability. Access is provided to the valves internal components for inspection or repair without disturbing the process or bypass piping. Figure 11 illustrates a valve designed to be serviced in-line.

SAFETY SHUTDOWN SYSTEMS

These controls are normally provided as backup pump protection for the continuous bypass and automatic bypass control systems. They should only operate if the normal system fails due to mechanical or operator causes. In each case, the protection system trips the pump off.

Head This requires only an accurate pressure switch, set for a discharge pressure corresponding to the total pump head when the pump is close to the shutoff capacity. For conservative results, calculate based on minimum suction pressure. To use this method, the pump characteristic must rise continuously to shutoff. Control circuitry may require delays to reject spurious pressure surges.

Temperature A temperature sensor mounted on the pump casing or in the discharge and close to the pump can signal for a shutdown of all or some of the operating pumps. The trip can be on either a high temperature sensing or a high differential temperature sensing between inlet and discharge. This method can protect against large temperature rises (occurring at perhaps 5% or less of capacity) but is less sensitive to smaller rises at higher percentages of capacity where adverse hydraulic effects begin for large and high-power pumps.

Low-Flow Systems These protection systems can be configured in various ways. A low-flow switch can trip the pump off at a predetermined setpoint. A flow meter can signal a controller to shut down the pump. If this protection circuit is installed, the pump start circuit must temporarily bypass this trip in order to start the pump. This is normally accomplished by a spring-loaded switch that bypasses the low-flow trip when held in the "Start" position, but activates the trip protection in the "Run" position.

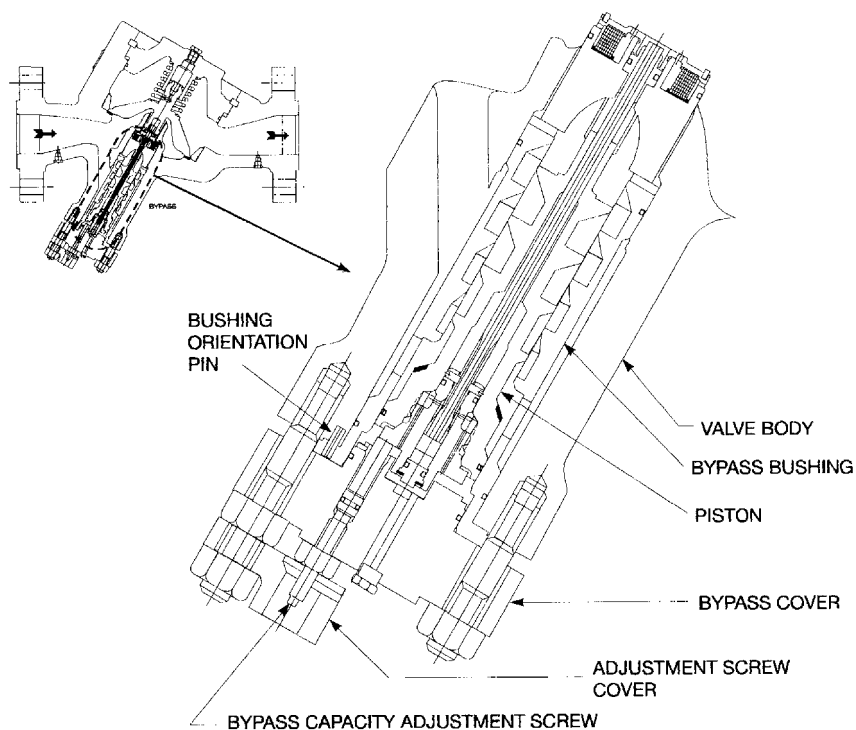

FIGURE 10 Pilot operated multistage bypass trim actuated by an in-line pilot valve

FIGURE 11 Typical in-line serviceable ARC valve

OTHER BYPASS SYSTEM HARDWARE

Orifices In high pressure applications, the system often does not provide adequate pressure in the bypass line to prevent cavitation or flashing. Either of these conditions is undesirable because it can cause damage to both valves and the pipe system or cause a reduction in flow below the minimum desired, jeopardizing the pump protection system. All pressure-reducing valves will experience a velocity-induced recovery effect that will limit the amount of pressure drop a valve can take and cause a reduction in flow capacity.

The requirement of backpressure is generic to all pressure-reducing applications. Pressure reduction even by multiple stage cascading can minimize the requirement; however, no valve design will redefine a fluid's physical properties. This becomes especially important in modulating systems. A fixed orifice will not provide the proper backpressure at all flow levels.

As the flow in the bypass line is reduced, the orifice becomes less effective. Proper system design should be used to optimize valve pressure reduction and consider all fluid dynamic effects downstream of any pressure-reducing device. When adequate backpressure is not available downstream of a pressure reducing valve, vapor bubbles will form in the zone just downstream of the valve last stage control surface. This zone is defined as the "Vena Contracta" and represents the point of highest fluid velocity and lowest pressure.

The potential for 1) damage to downstream piping components and 2) flow reduction exists from this point. When line pressure remains below the fluid vapor pressure, any existing bubbles will remain and expand as piping friction further reduces line pressure. This can be defined as "*flashing condition*" and is characterized by a polished appearance on affected surfaces. When the line pressure drops below the fluid vapor pressure and then recovers, any entrapped vapor bubbles will collapse (implode). This is defined as a "*cavitating condition*" and is characterized by a cinder-like appearance on affected surfaces. The resolution of either condition is best addressed by eliminating vapor formation. This can be assured by the provision of adequate back pressure through the use of a fixed or variable orifice.

Fixed Orifice Simple, easily replaced orifices that reduce the pressure are an effective way to reduce bypass head and provide adequate backpressure in bypass systems. Several stages may be necessary, however, to break down high-pressure drops without flashing. For calculations of flow through standard-shaped orifices, see Section 8.1 and 8.2.

Coefficients of discharge for oddly shaped multistage orifices are difficult to calculate. However, manufacturers of these specialties can furnish curves of delivery as a function of pressure.

Variable Orifice In modulating systems, a fixed orifice will not provide the proper backpressure over a wide flow range. A backpressure regulator (BPR) has a variable orifice with a spring-loaded plunger that is designed to open at a specified differential pressure. If flow and differential pressure increase, it opens further to maintain the differential pressure and backpressure constant. Figure 12 illustrates a typical BPR construction. Figure 13 shows a standard BPR installation. The BPR is normally located as close to the receiver vessel as possible so that the correct backpressure is maintained in the entire bypass line.

Valves, Piping, and Fittings For cold water at low pressure, a simple power-actuated globe-type bypass valve is often adequate. In modulating bypass systems, the bypass valve must resist throttling damage, particularly if the water is hot. Staging the pressure drop in the valve is the most common way to reduce or eliminate flashing and cavitation damage to the valve trim or body. Figure 14 illustrates a typical multi-stage pressure reducing valve (PRV).

Pressure is reduced in stages to ensure that the pressure never decreases below the fluid vapor pressure. This prevents cavitation and the resultant valve damage and noise. Figure 15 illustrates typical calculations for reducing pressure in sequential stages. Refer to Chapter 7 for detailed information regarding valve sizing and selection.

FIGURE 12 Construction of a typical backpressure regulator

FIGURE 13 Backpressure regulator installation

Pipe material like that used for the main discharge is adequate for nearly all of the bypass line. Near the orifice and control valve outlets, however, heavier wall or higher chrome content will lengthen life. Welded piping is common for high pressures. To prevent erosion, pipe fittings (especially elbows) should not immediately follow an orifice.

Flow Meters Flow rate is the variable that must be measured for most automatic bypass multi-component control systems. The meter may have any type of primary element that will produce an accurate signal at the process flow for which the bypass must be controlled.

A simple orifice meter or venturi tube is commonly used. The user must have the required straight upstream and downstream pipe lengths or use flow straighteners to obtain an accurate reading. The device must be properly sized to provide both accurate indication at relatively low process flows and satisfactory pressure drop at maximum process flow conditions.

Flow meters can be located either upstream or downstream of the pump. Meters located upstream are at lower internal pressure but are larger in diameter with larger flanges. In addition, pressure drop at rated flow is important to avoid low pump *NPSH*. Meters located downstream are normally smaller but must be rated for the maximum pump discharge pressure.

FIGURE 14 Construction of a typical multistage pressure-reducing valve

Controls Controls range in complexity from a simple pressure switch that stops a pump drive motor to modulating systems that meter flow and maintain a selected minimum flow through the pump. The control system may have to provide a deadband near the opening point and be sufficiently stable to hold bypass flow nearly constant in spite of erratic flow during upsets and startup.

For example, when the primary flow-measuring element is upstream of the bypass branch off, sufficient decrease in flow will cause the bypass control to open in an “On-Off” bypass system. The main control valve, farther downstream, will then also open to maintain flow to the boiler or process. The primary element will sense the added flow and, in a simple bypass control system, close the bypass valve, initiating hunting in flow and valve action. To prevent this, the setpoint for bypass valve closing must be greater than twice the minimum bypass flow. If minimum flow is in the 30–50% range, this wastes energy during bypass. This control problem is avoided if a modulating system is installed.

SPECIAL BYPASS SYSTEMS

Pumps in Parallel It is possible to provide a single bypass valve for two or more pumps, as shown in Figure 16. The bypass line and valve must be able to handle simultaneously

FIGURE 15 Calculations for pressure reduction through a multistage valve

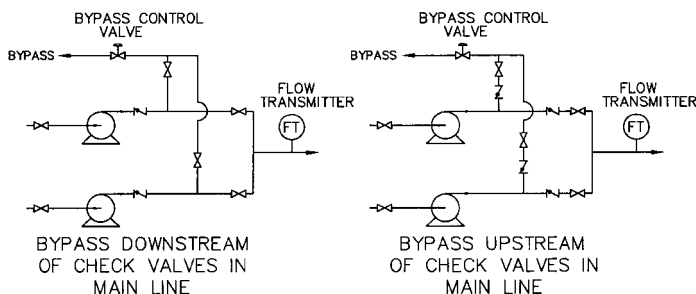

FIGURE 16 Examples of a single bypass valve that provides minimum flow control for two parallel pumps

the total bypass flow of all pumps. The pumps must operate together and they must have identical head-capacity curves. If they do not, the bypass flow will differ between pumps. The pump with the lower head may have insufficient bypass flow or could be completely shut off.

In the system of Figure 16 (left), the main line check valve prevents backflow through an idle pump. If the branch off were installed as shown in Figure 16 (right), an additional check valve in each bypass connection would be necessary to stop the backflow. Therefore, this latter configuration is not recommended.

An alternative arrangement that provides better operational flexibility and pump protection is illustrated in Figure 17. Each pump is individually protected by its own automatic recirculation control (ARC) valve. Pumps can be operated individually or in any combination and the pump head characteristic curves do not have to be identical.

Pumps in Series A single bypass line and valve can protect two pumps in series (see Figure 18). The designer must provide for the larger of the two separately evaluated bypass flows and must take into account the heating effect of the upstream pump. The pumps cannot operate singly unless additional piping and controls are installed.

FIGURE 17 Multiple parallel pumps individually protected by ARC valves

FIGURE 18 Example of a single bypass line that protects two pumps in series

VARIABLE SPEED PUMP BYPASS CONSIDERATIONS

Large horsepower pumps are often powered by steam turbines or with motors connected through a variable speed coupling. The effect of decreased speed and discharge head is to reduce the minimum flow requirement for the pump. Therefore, if the minimum required bypass flow is calculated and sized with the pump at normal operating speed and pressure, the bypass flow will be adequate when the pump is operated at lower speeds.

Warning If a constant backpressure device such as a backpressure regulator is used to control bypass pressure, precautions must be taken to ensure that the pump is never operated at pressures below the BPR setting. If the pump is operated below the BPR setting, the pump will have no bypass flow and may be damaged in a short time.

In a typical boiler system, a constant speed booster pump, requiring less minimum flow than the boiler-feed pump, could be protected by the bypass flow for the variable speed boiler feed pump. The designer must determine if the booster pump bypass flow is sufficient when the high pressure feed pump is running at minimum discharge pressure.

SECTION 2.4

CENTRIFUGAL PUMP PRIMING

IGOR J. KARASSIK
C. J. TULLO

A centrifugal pump is primed when the passageways of the pump are filled with the liquid to be pumped. The liquid replaces the air, gas, or vapor in the passageways. This may be done manually or automatically.

When a pump is first put into service, its passageways are filled with air. If the suction supply is above atmospheric pressure, this air will be trapped in the pump and compressed somewhat when the suction valve is opened. Priming is accomplished by venting the entrapped air out of the pump through a valve provided for this purpose.

Unlike a positive displacement pump, a centrifugal pump that takes its suction from a supply located below the pump, which is under atmospheric pressure, cannot start and prime itself (unless designed to be self-priming, as described later in this section). At its rated capacity, a positive displacement pump will develop the necessary pressure to exhaust air from its chambers and from the suction piping. Centrifugal pumps can also pump air at their rated capacity, but only at a pressure equivalent to the rated head of the pump. Because the specific weight of air is approximately $\frac{1}{800}$ that of water, a centrifugal pump can produce only $\frac{1}{800}$ of its rated liquid pressure. For every 1 ft (1 m) water has to be raised to prime a pump, the pump must produce a discharge head of air of approximately 800 ft (m). It is therefore apparent that the head required for a conventional centrifugal pump to be self-priming and to lift a large column of liquid (and in some cases to discharge against an additional static liquid head) when pumping air is considerably greater than the rating of the pump. Centrifugal pumps that operate with a suction lift can be primed by providing (1) a foot valve in the suction line, (2) a single-chamber priming tank in the suction line or a two-chamber priming tank in the suction and discharge lines, (3) a priming inductor at the inlet of the suction line, or (4) some form of vacuum-producing device.

FOOT VALVES

A foot valve is a form of check valve installed at the bottom, or foot, of a suction line. When the pump stops and the ports of the foot valve close, the liquid cannot drain back to the suction well if the valve seats tightly. Foot valves were very commonly used in early installations of centrifugal pumps. Except for certain applications, their use is now much less common.

A foot valve does not always seat tightly, and the pump occasionally loses its prime. However, the rate of leakage is generally small, and it is possible to restore the pump to service by filling and starting it promptly. This tendency to malfunction is increased if the liquid contains small particles of foreign matter, such as sand, and foot valves should not be used for such service. Another disadvantage of foot valves is their unusually high frictional loss.

The pump can be filled through a funnel attached to the priming connection or from an overhead tank or any other source of liquid. If a check valve is used on the pump and the discharge line remains full of liquid, a small bypass around the valve permits the liquid in the discharge line to be used for repriming the pump when the foot valve has leaked. Provision must be made for filling all the passageways and for venting out the air.

PRIMING CHAMBERS

The Single-Chamber Tank A single-chamber primer is a tank with a bottom outlet that is level with the pump suction nozzle and directly connected to it. An inlet at the top of the tank connects with the suction line (Figure 1). The size of the tank must be such that the volume contained between the top of the outlet and the bottom of the inlet is approximately three times the volume of the suction pipe. When the pump is shut down, the liquid in the suction line may leak out, but the liquid in the tank below the suction inlet cannot run back to the supply. When the pump is started, it will pump this entrapped liquid out of the priming chamber, creating a vacuum in the tank. The atmospheric pressure on the supply will force the liquid up the suction line into the priming chamber.

FIGURE 1 Single-chamber priming tank

Each time the pump is stopped and restarted, a quantity of liquid in the priming tank must be removed to create the required vacuum. Because of possible back siphoning, the liquid volume in the tank is reduced. Unless the priming tank is refilled, it has limited use. Automatic refilling of the priming tank cannot occur if the pump has a discharge check valve unless there is sufficient backflow from the discharge system before the check valve seats.

Because of their size, the use of single-chamber priming tanks is restricted to installations of relatively small pumps, usually to a 12-in (305-mm) suction line (approximately 2000 gpm [450 m³/h]).

The Two-Chamber Tank This type of priming tank is an improvement over the single-chamber design. It consists of integral suction and discharge chambers connected by a vacuum breaker or equalizing line. The operation and automatic refilling feature of this device are shown in Figure 2. Commercial priming chambers are readily available with proper automatic vents and other features.

PRIMING INDUCTORS

If a separate source of liquid of sufficient capacity and pressure is available, it can be used to fill the suction line of the pump to be primed through the use of an inductor, as shown in Figure 3. For water, the pressure must be equal to about 4 lb/in² for each foot (90 kPa for each meter) of head necessary to prime the pump, measured from the lowest liquid level in the sump from which priming must be accomplished to the top of the pump. The amount of liquid necessary depends on the pressure.

Because the inductor is a positive-pressure device, leaks in the suction line or at the pump seal or stuffing box are not critical. The service liquid can be left on or turned off

Phantom View of Primer in Use with Pump Stopped (left)

When the pump stops, the liquid in the upper chamber runs back into the pump and lower chamber of primer by gravity, thus refilling them with liquid and keeping the pump always ready for starting.

Phantom View of Primer in Use with Pump Running (right)

When the pump starts, it draws liquid from the lower chamber and discharges it through the upper chamber. Withdrawal of liquid from the lower chamber creates a partial vacuum in this chamber, which causes the liquid in the sump or well to rise in the suction pipe and flow through the primer to the pump.

FIGURE 2 Two-chamber priming tank (Apco/Valve and Primer)

FIGURE 3 Priming inductor (Nagle Pumps)

FIGURE 4 Arrangement of priming with an ejector

after pumping is initiated. If left on, the head developed by the pump (therefore the flow also) will be increased.

An additional feature of the priming inductor is that operation is possible even when the suction line is covered with sediment. When the pump and suction line are filled, back-flow results, mixing the solids and the liquid.

TYPES OF VACUUM DEVICES

Almost every commercially made vacuum-producing device can be used with systems in which pumps are primed by evacuation of air. Formerly water-jet, steam-jet, or air-jet primers had wide application, but with the increase in the use of electricity as a power source, motor-driven vacuum pumps have become more popular.

Ejectors Priming ejectors work on the jet principle, typically using steam, compressed air, or water as the operating medium. A typical installation for priming with an ejector is shown in Figure 4. Valve V_1 is opened to start the ejector, and then valve V_2 is opened. When all the air has been exhausted from the pump, liquid will be drawn into and discharged from the ejector. When this occurs, the pump is primed and valves V_2 , and V_1 are closed, in that order.

An ejector can be used to prime a number of pumps if it is connected to a header through which the individual pumps are vented through isolating valves.

Dry Vacuum Pumps Dry vacuum pumps, which may be of either the reciprocating or the rotary oil-seal type, cannot accommodate mixtures of air and liquid. When they are used in priming systems, some protective device must be interposed between the centrifugal pump and the dry vacuum pump to prevent liquid from entering the vacuum pump. The dry vacuum pump is used extensively for central priming systems.

Wet Vacuum Pumps Any rotary, rotative, or reciprocating pump that can handle air or a mixture of air and liquid is classified as a wet vacuum pump. The most common type

FIGURE 5 Operating principle of the Nash Hytor pump (Nash Engineering)

used in priming systems is shown in Figure 5. This is a centrifugal displacement type of pump consisting of a round, multiblade rotor revolving freely in an elliptical casing partially filled with liquid. The curved rotor blades project radially from the hub and, with the side shrouds, form a series of pockets and buckets around the periphery.

The rotor revolves at a speed high enough to throw the liquid out from the center by centrifugal force. This forms a solid ring of liquid revolving in the casing at the same speed as the rotor, but following the elliptical shape of the casing. It will be readily seen that this forces the liquid to alternately enter and recede from the buckets as the rotor at high velocity.

Referring to Figure 5 and following through a complete cycle of operation in a given chamber, we start at point A with the chamber (1) full of liquid. Because of the effect of the centrifugal force, the liquid follows the casing, withdraws from the rotor, and pulls air through the inlet port, which is connected to the pump inlet. At (2) the liquid has been thrown outwardly from the chamber in the rotor and has been replaced with air. As rotation continues, the converging wall of the casing at (3) forces the liquid back into the rotor chamber, compressing the air trapped in the chamber and forcing it out through the discharge port, which is connected with the pump discharge. The rotor chamber is now full of liquid and ready to repeat the cycle. This cycle takes place twice in each revolution.

If a solid stream of liquid circulates in this pump in place of air or of an air and liquid mixture, the pump will not be damaged but it will require more power. For this reason, in automatic priming systems using this type of vacuum pump, a separating chamber or trap is provided so liquid will not reach the pump. Liquid needed for sealing a wet vacuum pump can be supplied from a source under pressure, with the shutoff valve operated manually or through a solenoid connected with the motor control. It is, however, preferable to provide an independent sealing liquid supply by mounting the vacuum pump on a base containing a reservoir. This is particularly desirable in locations where freezing may occur, as a solution of antifreeze can be used in the reservoir.

CENTRAL PRIMING SYSTEMS

If there is more than one centrifugal pump to be primed in an installation, one priming device can be made to serve all the pumps. Such an arrangement is called a central priming system (Figure 6). If the priming device and the venting of the pumps are automatically controlled, the system is called a central automatic priming system.

Vacuum-Controlled Automatic Priming System A vacuum-controlled automatic priming system consists of a vacuum pump exhausting a tank. The pump is controlled by

FIGURE 6 Connections for a central priming system

FIGURE 7 Vacuum-controlled central automatic priming

a vacuum switch and maintains a vacuum in the tank of 2 to 6 in Hg (50 to 150 mm Hg) above the amount needed to prime the pumps with the greatest suction lift. The priming connections on each pump served by the system are connected to the vacuum tank by automatic vent valves and piping (Figure 7). The vacuum tank is provided with a gage glass and a drain. If liquid is detected in the vacuum tank as the result of leakage in a vent valve, the tank can be drained. Automatic vent valves consist of a body containing a float that actuates a valve located in the upper part. The bottom of the body is connected to the space being vented. As air is vented out of the valve, water rises in the body until the float is lifted, and the valve is closed.

A typical vent valve designed basically for vacuum priming systems is illustrated in Figure 8. The valve is provided with auxiliary tapped openings on the lower part of the body for connection to any auxiliary vent points on the system—for instance, when air is to be exhausted simultaneously from the high point of the discharge volute and the high point of the suction passageways. When one or more of these vent points are points of higher pressure, such as the top of the volute of the pump, an orifice is used in the vent line to limit the flow of liquid. Otherwise, a relatively high constant flow of liquid from the discharge back to the suction would take place, causing a constant loss. Where a unit is used more or less constantly, a separate valve should be used for each venting point.

The system shown in Figure 7 is the most commonly used of central automatic priming systems. It can use either wet or dry motor-driven vacuum pumps. Most central priming systems are provided with two vacuum pumps. The usual practice is to have the control of one vacuum pump switched on at some predetermined vacuum and the control of the second switched on at a slightly lower vacuum.

Combination dry reciprocating-type vacuum pump and vacuum tank units are commercially available in various sizes. The operation of a typical unit can be explained as follows, referring to Figure 9.

The primer automatically stops and start itself to maintain a minimum vacuum in its tank at all times, regardless of whether the centrifugal pumps it serves are operating or not.

A vacuum header is run from the primer to the centrifugal pumps, and connection is made to the priming valve mounted on each pump. The vacuum in the primer tank

FIGURE 8 Automatic vent valve (Nash Engineering)

removes the air from the pump and suction line via the vacuum header and priming valve. Liquid rises up the suction line and fills the pump. The liquid cannot enter the vacuum header because the float mechanism in the priming valve closes when the liquid reaches it.

If, for any reason, the liquid level in the pump drops, the priming valve immediately opens and the vacuum restores the liquid level.

The pumps are thus kept permanently primed.

Automatic priming systems using ejectors are also feasible, and several such systems are commercially available.

SELF-CONTAINED UNITS

Centrifugal pumps are available with various designs of priming equipment that makes them self-contained units. Some have automatic priming devices, which are basically attachments to the pump and become inactive after the priming is accomplished. Other units, which are self-priming pumps, incorporate a hydraulic device that can function as a wet vacuum pump during the priming period (see below). For stationary use, the automatically primed type is more efficient. The self-priming designs are generally more compact and are preferred for portable or semiportable use.

FIGURE 9 Combination dry reciprocating-type vacuum pump and vacuum tank (Apco/Valve and Primer)

An automatically primed motor-driven pump uses a wet vacuum pump either directly connected to the pump or driven by a separate motor. In a directly connected unit, as soon as the centrifugal pump is primed, a pressure-operated control opens the vacuum pump suction to atmosphere so it operates unloaded. With a separately driven vacuum pump, the controls stop the vacuum pump when the centrifugal pump is primed.

SELF-PRIMING PUMPS

The basic requirement for a self-priming centrifugal pump is that the pumped liquid must be able to entrain air in the form of bubbles so the air will be removed from the suction side of the pump. This air must be allowed to separate from the liquid after the mixture of the two has been discharged by the impeller, and the separated air must be allowed to escape or to be swept out through the pump discharge. Such a self-priming pump therefore requires, on its discharge side, an air-separator, which is a relatively large stilling chamber, or reservoir, either attached to or built into the pump casing. Alternatively, a small air bleed line can be installed from the discharge pipe between the pump and the discharge check valve back to the suction source.

There are two basic variations of the manner in which the liquid from the discharge reservoir makes the pump self-priming: (1) recirculation from the reservoir back to the suction and (2) recirculation within the discharge and the impeller itself.

Recirculation to Suction In such a pump, a recirculating port is provided in the discharge reservoir, communicating with the suction side of the impeller. Before the first time the pump is started, the reservoir is filled. As the pump is started, the impeller handles whatever liquid comes to it through the recirculating port plus a certain amount of air from the suction line. This mixture of air and liquid is discharged to the reservoir, where the two elements are separated, the air passing out of the pump discharge and the liquid returning to the suction of the impeller through the recirculation port. This operation continues until all the air has been exhausted from the suction line.

The vacuum thus produced draws the liquid from the suction supply up the suction piping and into the impeller. After all the air has been exhausted and liquid is drawn into the pump, the pressure difference between the pump body and the inlet causes the priming valve, which permits communication between discharge and suction passages, to close. It is essential that the reservoir in the suction side remain filled with liquid when the pump is stopped, so the pump is ready to restart. This is accomplished by incorporating either a valve or some sort of trap between the suction line and the impeller.

Pumps with recirculation to suction are seldom used today, and by far the most common arrangement is that with recirculation at the discharge.

Recirculation at Discharge This form of priming is distinguished from the preceding method by the fact that the priming liquid is not returned to the suction of the pump but mixes with the air either in the impeller or at its periphery. The principal advantage of this method, therefore, is that it eliminates the complexity of internal valve mechanisms.

One such self-priming pump is illustrated in Figure 10. An open impeller (A) rotates in a volute casing (B), discharging the pumped liquid through passage C into the reservoir (D). When the pump starts, the trapped liquid carries entrained air bubbles from the suction to the discharge chamber. There, the air separates from the liquid and escapes,

FIGURE 10 Self-priming pump with recirculation at discharge (Flowserve Corporation)

FIGURE 11 Self-priming pump with recirculation at discharge (Peabody Barnes)

whereas the liquid in the reservoir returns to the impeller through the recirculation port (F), reenters the impeller and, after mixing once more with air bubbles, is discharged through passage C. This operation is repeated continuously until all the air in the suction line has been expelled. After the pump is primed, a uniform pressure distribution is established around the impeller, preventing further recirculation. From this moment on, the liquid is discharged into the reservoir bath at C and at F.

Figure 11 illustrates another form of self-priming pump with recirculation at the discharge. In this arrangement, the return of the liquid to the impeller periphery takes place through a communicating passage (A) located at the bottom of the pump casing. After the pump is primed, liquid is delivered into the reservoir at the discharge both through its normal volute discharge and through port A. In the pump illustrated in Figure 11, a check valve at the pump suction (B) acts to prevent the draining of the pump after it has been stopped.

Regenerative Turbine Pumps Because these pumps can handle relatively large amounts of gas, they are inherently self-priming as long as sufficient liquid remains in the pump to seal the clearance between the suction and discharge passages. This condition is usually met by building a trap in the pump suction.

SPECIAL APPLICATIONS

Systems for Sewage Pumps A pump handling sewage or similar liquids containing stringy material can be equipped with automatic priming, but special precautions must be used to prevent carry-over of the liquid into the vacuum-producing device.

One approach is to use a tee on the suction line immediately adjacent to the pump suction nozzle, with a vertical riser mounted on the top outlet of the tee. This riser is blanked at the top, thus forming a small tank. The top of the tank is vented to a vacuum system through a solenoid valve. The solenoid valve in turn is controlled electrically through electrodes located at different levels in the tank. The solenoid valve closes if the liquid reaches the top electrode and opens if the liquid level falls below the level of the lower electrode.

Another solution permits the use of an automatic priming system with a separate motor-driven vacuum pump controlled by a discharge-pressure-actuated pressure switch. An inverted vertical loop is incorporated in the vacuum pump suction line to the pump

FIGURE 12 Air-separating chamber

being primed. This prevents the sewage from being carried over into the vacuum pump because this pump shuts down before the liquid reaches the top of the loop.

Systems for Air-Charged Liquids Some types of liquid have considerable dissolved gas that is liberated when the pump handles a suction lift. In such installations, an air-separating tank (also called a *priming tank* or an *air eliminator*) should be used in the suction line. One type (Figure 12) uses a float-operated vent valve to permit the withdrawal of air or other gas. Another common arrangement uses a float valve mounted on the side of the tank to directly control the starting and stopping of the vacuum pump. Unless the air-separating tank is relatively large and the vacuum pump is not oversized, there is danger of frequent starting and stopping of the vacuum pump in such a system. When sand is present as an impurity in the liquid, the air-separating tank can be made to also function as a sand trap.

Systems for Units Driven by Gasoline or Diesel Engines An automatic priming system using motor-driven vacuum pumps can be used for centrifugal pumps driven by diesel engines if a reliable source of electric power is available in the station. An auxiliary vacuum pump driven by a gasoline engine might be desirable for emergency use in case of electric power failure. Alternatively, a direct-connected wet vacuum pump with controls similar to those used in motor-driven automatically primed units is very satisfactory.

The choice of the priming device for a gasoline-engine centrifugal pump depends on the size of the pump, the required frequency of priming, and the portability of the unit. Most portable units are used for relatively low heads and small capacities, for use in pumping out excavations and ditches, for example. Self-priming pumps of various types are most satisfactory for this service and are preferable to regular centrifugal pumps.

It is possible to utilize the vacuum in the intake manifold of a gasoline engine as a means of priming or keeping the pump primed. The rate at which the air can be drawn

from the pump in this manner is relatively low, so many of these units use foot valves. They are initially primed by filling the pump manually. Provision must be made to prevent liquid from being drawn over into the manifold.

TIME REQUIRED FOR PRIMING

The time required to prime a pump with a vacuum-producing device depends on (1) the total volume to be exhausted, (2) the initial and final vacuums, and (3) the capacity of the vacuum-producing device over the range of vacuums that will exist during the priming cycle. The calculations for determining the time necessary to prime a pump are complicated. To permit close approximations, jet primers are usually rated in net capacity for various lifts. It is necessary to divide the volume to be exhausted by the rating to obtain the approximate priming time. Unless such a simplified method is available, the selection of the size of a primer is best left to the vendor of the equipment.

Central automatic priming systems are usually rated for the total volume to be kept primed. The time initially required to prime each unit served by the central system is not usually considered, as the basic function of the system is to keep the pumps primed and in operating condition at all times.

PREVENTION OF UNPRIMED OPERATION

Various controls may be used to prevent the operation of a pump when it is unprimed. These controls depend upon the type of priming system used. For many installations, a form of float switch in a chamber connected with the suction line is used. If the level in the chamber is above the impeller eye of the pump, the float switch control allows the pump to operate. If the liquid falls below a safe level, the float switch acts through the control to stop the pump, to prevent its being started, to sound an alarm, or to light a warning lamp. Such a valve and switch are illustrated in Figure 13.

FIGURE 13 Priming valve with liquid level control switch (Apco/Valve and Primer)

GENERAL

Because a great number of automatic priming devices and systems are available, care should be taken to use the type or variation best suited to the application. The discussion of priming in this section does not, of course, cover all makes and modifications available for every specific application.

An automatic priming system will often allow units to be operated with excessive air leakage into the suction lines. This is poor practice because it requires the operation of the vacuum producer for greater periods of time than normally necessary.

DISPLACEMENT PUMPS

SECTION 3.1

POWER PUMP THEORY

WILLIAM K. CHAPLIS
FREDERIC W. BUSE

A power pump is a positive displacement machine consisting of one or more cylinders, each containing a piston or plunger. The pistons or plungers are driven through slider-crank mechanisms and a crankshaft from an external source. The capacity of a given pump is governed by the rotational speed of the crankshaft.

Unlike a centrifugal pump, a power pump does not develop pressure; it only produces a flow of fluid. The downstream process or piping system produces a resistance to this flow, thereby generating pressure in the piping system and discharge portion of the pump. The flow fluctuates at a rate proportional to the pump speed and number of cylinders. The amplitude of the fluctuations is a function of the number of cylinders. In general, the greater the number of cylinders, the lower the amplitude of the flow variations at a specific rpm.

All power pumps are capable of operating over a wide range of speeds, thereby making it possible to produce a variable capacity when coupled to a variable speed drive. Each pump has maximum suction and discharge pressure limits that, when combined with its maximum speed, determine the pump's power rating. The pump can be applied to power conditions that are less than its maximum rating but at a slight decrease in mechanical efficiency.

The power pump is a positive displacement device. When operating, it will continue to deliver flow independent of the pressure in the discharge piping system. Unlike a centrifugal pump, a power pump will not "deadhead" or "go back on its curve" in response to increasing discharge pressure. When this pressure exceeds the design limits of the pump, mechanical failure—often catastrophic—will result. For this reason, all piping systems incorporating power pumps must have discharge pressure relief devices to limit the pressure in the piping system and avoid pump failure. These devices must be located between the discharge connection on the pump and the first isolation valve in the piping system.

This section has been organized to provide sufficient power pump theory to properly select a pump for most applications. It is recognized that the proper pump metallurgy for the pumped fluid must be used, but due to the vast number of possible fluids, selection of pump metallurgy is outside the scope of this section.

The subject of Net Positive Suction Head (NPSH) is mentioned in several places in this section and is covered in more detail in Section 3.4, "Displacement Pump Performance, Instrumentation, and Diagnostics." For basic power pump selection, it is only necessary to understand that the NPSH available from the suction system must be sufficiently above the NPSH required by the pump to operate properly.

SELECTION THEORY

Power Brake horsepower (bhp) is a function of a pump's capacity, differential pressure, and mechanical efficiency. It is an essential criterion for selecting the drive components but is not valuable for pump selection. A large pump operating well below its design rating can meet the same horsepower requirements as a smaller pump running at a higher speed. Unless the application requires a derated pump, it is usually more economical to select a pump at the upper end of its design rating.

The brake horsepower for the pump is

$$\text{In USCS units} \quad bhp = Q \times Ptd / 1714 \times ME$$

$$\text{In SI units} \quad kW = Q \times Ptd / 36 \times ME$$

where Q = delivered capacity, gpm (m^3/h)

Ptd = differential pressure (discharge – suction), lb/in² (bar)

ME = mechanical efficiency, %

NOTE: One bar equals 10^5 Pa.

Capacity The capacity Q is the total volume of fluid delivered per unit of time. This fluid includes liquid, entrained gases, and solids at the specified conditions.

Displacement Displacement D , gpm (m^3/h), is the calculated capacity of the pump with no slip losses. For single-acting plunger or piston pumps, this is

$$\text{In USCS units} \quad D = A \times m \times n \times s / 231$$

$$\text{In SI units} \quad D = A \times m \times n \times s \times 6 \times 10^{-5}$$

where A = cross-sectional area of plunger or piston, in² (mm²)

m = number of plungers or pistons

n = rpm of pump

s = stroke of pump, in (mm) (half the linear distance the plunger moves in one revolution)

231 = in³/gal

For double-acting plunger or piston pumps, this is

$$\text{In USCS units} \quad D = (2A - a)m \times n \times s / 231$$

$$\text{In SI units} \quad D = (2A - a)m \times n \times s \times 6 \times 10^{-5}$$

where a is the cross-sectional area of the piston rod, in² (mm²).

Pressure The pressure Ptd used to determine brake horsepower is the differential pressure or discharge pressure minus the suction pressure. In most applications, the suction pressure is small relative to the discharge pressure. However, when pumping some compressible liquids, such as methane and propane, the suction pressure may be 20 to 30% of the discharge pressure. For accurate brake horsepower calculations, always include the suction pressure. Figure 1 shows a typical performance curve for a power pump.

FIGURE 1 Typical power pump performance: brake horsepower versus gallons per minute (kilowatts versus m³/h) based on zero slip (Flowserve Corporation)

TABLE 1 Slip in a pump with a plate valve

| Centistokes | 100 | 1,000 | 2,000 | 6,000 | 10,000 | 12,000 |
|-------------|-----|-------|-------|-------|--------|--------|
| Slip, % | 8 | 8.5 | 9.5 | 20 | 41 | 61 |

TABLE 2 Slip as a function of pump speed and pressure

| Pressure, lb/in ² (bar) | Slip, % | | |
|------------------------------------|------------|------------|------------|
| | At 440 rpm | At 390 rpm | At 365 rpm |
| 4000 (275) | 11 | 22 | 34 |
| 3000 (207) | 9 | 20 | 31 |
| 2000 (138) | 7 | 18 | 30 |
| 1000 (69) | 7 | 15 | 27.5 |

Slip Slip (S) is the loss of capacity due to internal and external pump leakage. External leakage occurs primarily through the stuffing box via the packing. Internal leakage is primarily the backflow past the suction and discharge valves. Backflow occurs when a valve remains open for a fraction of a second as the plunger or piston reverses direction. A small amount of leakage may occur across the piston in a double acting pump from the high pressure side to the low pressure side. Slip is expressed as a percentage loss of the suction capacity and is typically 1% to 4%:

$$S = B + V + L$$

where S = Slip, %

B = Leakage through the stuffing box

V = Backflow across the valves

L = Internal leakages

Fluid viscosity, pump speed, and discharge pressure can all have an effect on slip, which is shown in Tables 1 and 2.

Mechanical Efficiency The mechanical efficiency of a power pump is

In USCS units $ME = \text{power out}/\text{power in} = P_{out}/P_{in} = Q \times Pdt/1714 \times P_{in}$

In SI units $ME = \text{power out}/\text{power in} = P_{out}/P_{in} = Q \times Pdt/36 \times P_{in}$

where P_{in} is the input power from the driver, bhp (kW).

The mechanical efficiency of a power pump is the sum of all the frictional losses in the fluid and power ends. These include the plungers and packing, the crossheads, the rod seals, and the bearings. The efficiency of a single acting pump often exceeds 90%, while a double-acting piston pump will be 88% due to the additional piston and rod seals. If the pump is equipped with internal gearing, an additional 2% loss is common.

Most power pumps are designed to accept a range of plunger or piston sizes. When the larger plungers are used, the increased diameter of the packing/seals and plunger/liners will result in higher frictional losses than with smaller components. As a rule, doubling the plunger/piston diameter will decrease the mechanical efficiency by 8%. Mechanical efficiency is also affected by speed and, to a lesser extent, by developed pressure, as indicated in Tables 3 and 4.

Speed Pump speed, or, more correctly, stroke rate, is one of the most critical selection criteria for power pumps. The rotating and reciprocating parts of the power end, as designated, are often capable of speeds twice that of the actual pump rating. The maximum pump speed is determined by the design of the fluid end, the hydraulic capability of the anticipated suction system, and the required life of the plungers, packing, and valves. Most power pump standards limit the plunger speed from 140 to 280 ft/min (0.71 to 1.42 m/s). The plunger speed is

In USCS units $Sp = s \times n/6$

In SI units $Sp = s \times n/30,000$

where Sp = plunger or piston speed, ft/min (m/s).

s = stroke of the pump, in (mm) (half of the linear distance the plunger or piston moves in one revolution)

n = rpm of pump

All pumps have a minimum speed limit, usually determined by a decrease in the adequate lubrication to the bearings in the power end.

Volumetric Efficiency Volumetric efficiency (VE) is the ratio of the discharge volume to the suction volume, expressed as a percentage, plus the slip. It is proportional to the ratio r and the developed pressure where r is the ratio of the internal volume of fluid between valves when the plunger or piston is at the top of the peak of its back stroke ($C + D$) to the plunger or piston displacement (D) (see Figure 2).

TABLE 3 The effect of speed on mechanical efficiency at a constant developed pressure

| % of full speed | 44 | 50 | 73 | 100 |
|-----------------|------|------|------|------|
| ME, % | 93.3 | 92.5 | 92.5 | 92.5 |

| % of full-load developed pressure | 20 | 40 | 60 | 80 | 100 |
|-----------------------------------|----|----|------|----|------|
| ME, % | 82 | 88 | 90.5 | 92 | 92.5 |

FIGURE 2 The ratio r (Flowservice Corporation)FIGURE 3 Volumetric efficiency (Flowservice Corporation) ($\text{lb/in}^2 \times 0.69 = \text{bar}$)

Since the discharge volume cannot be readily measured at discharge pressure, it is taken at suction pressure. Taking the discharge volume at the suction pressure results in a higher volumetric efficiency than using the calculated discharge volume at discharge pressure because of fluid compressibility. Compressibility becomes important when pumping water or other liquids over 6000 lb/in^2 (414 bar), and it should be taken into consideration when determining the actual delivered capacity into the discharge system.

Figure 3 shows the approximate volumetric efficiency for water (not including slip). Based on the expansion back to suction capacity,

$$VE = (1 - Ptd \times \beta \times r) / (1 - Ptd \times \beta) - S$$

Based on discharge capacity,

$$VE = (1 - Ptd \times \beta \times r) - S$$

where β is the compressibility factor of the liquid being pumped. Figure 4 shows approximate values of β for various liquids.

When the compressibility factor is not known, but the suction and discharge density can be determined in pounds per cubic foot, the following equations can be used for calculating VE :

Based on suction capacity,

$$VE = r - (p_d/p_s)(r - 1) - S$$

FIGURE 4 Compressibility factor (Flowserve Corporation) (bar $\times 14.5 = \text{lb/in}^2$)

Based on discharge capacity,

$$VE = 1 - r(1 - p_s/p_d) - S$$

where p_s = suction density

p_d = discharge density

S = slip

Torque The average torque required by a power pump is independent of the pump speed, assuming the suction and discharge pressures are held constant. This means that the pump is a “constant torque” device and, unlike a centrifugal pump, will have a flat speed-torque curve. The torque required at the input shaft is as follows:

In USCS units $M = p \times 5250/n$

In SI units $M = p \times 9.549/n$

where M = pump torque, lb-ft ($\text{N} \cdot \text{m}$)

n = speed, rpm

p = power, bhp (kW)

Break-away torque, or start-up torque, is the torque required to initiate the motion of the pump to enable it to accelerate to a constant speed. If the pump is started against an open bypass to pump suction, the torque requirement is 25% of the running torque. If the pump is started against full discharge pressure, the torque requirement is 125% of the running torque. When selecting a drive system, the break-away torque of the pump must be considered. Special “high torque” motors are often required if the pump is to be started under the load.

TABLE 5 The pulses per revolution and pulse amplitude for various pump types

| Pump Type | No. of Cylinders | Pulses per Rev. | Pulse Amplitude |
|---------------------------|------------------|-----------------|-----------------|
| Duplex, double-acting | 4 | 8 | +24% – 22% |
| Triplex, single-acting | 3 | 6 | + 6% – 17% |
| Quintuplex, single-acting | 5 | 10 | + 2% – 5% |
| Septuplex, single-acting | 7 | 14 | +1.2% – 2.6% |
| Nonoplex, single-acting | 9 | 18 | +0.6% – 1.5% |

TABLE 6 Guidelines for acceptable plunger speeds

| Fluid | Plunger Speed, ft/min (m/s) |
|---------------------------------|-----------------------------|
| Cold water | 315–354 (1.6–1.8) |
| Hot water 140–194 °F (60–90 °C) | 217–256 (1.1–1.3) |
| Hot water over 194 °F (90 °C) | 157–217 (0.8–1.1) |
| Salt water | 236–276 (1.2–1.4) |
| Cold oil | 315–354 (1.6–1.8) |
| Hot oil | 256–295 (1.3–1.5) |
| Crude oil | 217–276 (1.3–1.5) |
| Liquid ammonia | 197–236 (1.0–1.2) |
| Carbamate | 138–158 (0.7–0.8) |
| Slurry | 158–197 (0.8–1.0) |
| Fatty acid | 236–295 (1.2–1.5) |
| Light hydrocarbons | 177–236 (0.9–1.2) |
| Glycol | 256–295 (1.3–1.5) |
| High viscosity liquids | 138–197 (0.7–1.0) |

If a variable frequency drive (VFD) is used for pump speed/capacity control, torque fluctuations or pulsations may require the drive manufacturer to provide special electronic dampening circuits. The normal pulsating flow of the pump causes the input power to fluctuate at approximately the same magnitude as the flow pulses. The frequency of these pulses per revolution of the crankshaft is twice the number of cylinders (see Table 5).

If the pump has internal gearing, or if the pump is being driven by an external gear reducer, the torque pulsation values listed should be divided by the gear ratio.

Derating Power pumps can be derated in order to achieve acceptable performance or part life in a variety of special applications. The most common derating is pump speed. Experience has shown that the life of fluid-end expendable parts, such as plungers, packing, and valves, can be extended if the pump speed/plunger velocity is reduced when pumping certain fluids. Some guidelines for acceptable plunger speeds are shown in Table 6.

Pumping high-viscosity fluids may also require the speed of a power pump to be derated. Some attempts have been made to establish standards for speed derating as a function of the fluid viscosity. Unfortunately, these methods have been based on power pump designs that were established for water or similar low-viscosity services. If a pump has been designed specifically for a high-viscosity service, only moderate speed derating may be required. Generally, pumps designed with large internal fluid passages, low-valve velocities, and larger plungers or pistons will need less derating.

Power pumps should be derated for a rod load if system or process “upsets” cannot be avoided. These are usually applications where the gas content of the pumped fluid can lead to abnormal pressure pulsations or cavitations in the fluid cylinder.

FLUID END THEORY

Pumping Cycle Unlike the relatively smooth, continuous flow of fluid through a centrifugal pump, the flow of fluid through a power pump occurs in a transitory dynamic condition called a *pumping cycle*. The event that initiates this cycle is the linear movement of the plunger or piston. In Figure 5, r is the radius of the crank in feet (meters), L is the length of the connecting rod in feet (meters), C equals L/r , and ω equals $(2\pi/60) \times \text{rpm}$. Thus, X , the linear movement of the piston or plunger is

$$X = r \left[1 - \cos \theta + L \left(1 - \sqrt{1 - \frac{r^2}{L^2} (\sin \theta)^2} \right) \right]$$

As the plunger (or piston) withdraws from the fluid cylinder or pumping chamber, the volume of the cylinder increases. The pressure in the cylinder decreases in response to the increased volume. Since most of the fluids handled by power pumps are relatively incompressible, very little plunger movement is required to cause a pressure drop. When the cylinder pressure drops sufficiently below suction pressure, the differential pressure begins to open the suction valve. The valve opens gradually and smoothly at the start of the suction stroke because the velocity and acceleration of the plunger are small.

Fluid flows through the suction valve assembly, following the plunger and filling the cylinder. As the plunger decelerates at the end of the suction stroke, the suction valve gradually returns to its seat. Ideally, the suction valve is completely closed as the plunger comes to a stop.

The motion of the slider-crank mechanism causes the plunger to reverse direction and start its discharge stroke. The fluid trapped in the fluid cylinder is compressed until the cylinder pressure exceeds the discharge pressure by an amount sufficient to begin to open the discharge valve. As with the suction valve, the discharge valve continues to open until it reaches its travel limit or until the velocity of fluid through the valve becomes constant. As the plunger decelerates, the valve moves back toward its seat. Again, ideally, the discharge valve closes when the motion of the plunger stops.

The number of pumping cycles in a single revolution of the crankshaft is the same as the number of cylinders in the pump. Every cylinder will "pump" in a sequence determined by the "firing order" of the crankshaft. The cylinders are arranged in parallel, with each one discharging into a common discharge manifold. In industry terms, the pump is usually identified by the number of plungers or pistons on the crankshaft. They are the same for single- or double-acting pumps (see Table 7).

Pulsations The pulsating characteristics of the fluid flowing into and out of power pumps are significantly influenced by the number of plungers or pistons. Discharge flow pulsations are the most critical because of the high energy potential generated when the system resistance reacts with the flow to create pressure. Since the magnitude of the discharge pulsation is mostly affected by the number of cylinders, increasing the number of cylinders will reduce the flow pulsations.

FIGURE 5 Slider-crank mechanism

TABLE 7 Industry terms for the number of plungers or pistons

| Number | Term |
|--------|------------|
| 1 | Simplex |
| 2 | Duplex |
| 3 | Triplex |
| 4 | Quadruplex |
| 5 | Quintuplex |
| 6 | Sextuplex |
| 7 | Septuplex |
| 9 | Nonuplex |

**FIGURE 6** The discharge rate for a single double-acting pump (Flowserve Corporation)**FIGURE 7** The discharge rate for a triplex single acting pump (Flowserve Corporation)

The acceleration and velocity of the plunger or piston will determine the rate that the fluid is discharged from the cylinder. The approximate velocity of the plunger or piston is

$$S = \frac{dx}{dt} = r \left(\sin \theta + \frac{\sin 2\theta}{2C} \right) \omega$$

The approximate acceleration of the plunger or piston is

$$Cp = \frac{d^2x}{dt^2} = r \left(\cos \theta + \frac{\cos 2\theta}{C} \right) \omega^2$$

The momentary rate of discharge capacity is the cross-sectional area A of the plunger or piston times velocity:

$$\text{For single-acting plunger or piston} \quad A = 0.785 \times D^2$$

$$\text{For double-acting piston} \quad A - a = 0.785 (D^2 - d^2)$$

The total discharge Q is equal to ALS' , where S' is the number of effective strokes in a given time. The quantity Q is the area of the curve, the mean height of which is

$$\text{Total } Q/t = ALS'/t = ALS''$$

where S'' is the number of strokes per second and t is time in seconds.

Figures 6 and 7 show discharge rates for two types of pumps. Tables 8 and 9 show how variations from the mean are related to the change in the number of plungers with a C of

TABLE 8 The effect of the number of plungers on variations in capacity from the mean (C is approx. 6:1)

| Type | Number of Plungers | % Above Mean | % Below Mean | Total % | Plunger Phase |
|------------|--------------------|--------------|--------------|---------|---------------|
| Duplex | 2 | 24 | 22 | 46 | 180 deg. |

FIGURE 8 Force balance of a typical valve

approximately 6:1. This shows that pumps with an even number of cylinders have a higher flow variation than pumps with an odd number of cylinders. Table 9 shows the variations in a triplex with changes in $C = L/R$.

Valves A pump valve in its simplest form is a free-moving plug that is opened when the force of the liquid below the valve exceeds the force of the liquid above it. When the force above the valve becomes greater than the lower, the plug closes and forms an effective seal to fluid “backflow” and pressure loss. If the valve does not perform this function efficiently, the performance of the pump can be degraded to the point where no flow is produced.

A valve will be in equilibrium when the forces above and below the valve are balanced (see Figure 8):

$$\text{Equilibrium} = P_1 \times A_1 = P_2 \times A_2 + S_f + M$$

where P = the pressure below the valve

A = the area below the valve exposed to P

P = the pressure above the valve

A = the area above the valve exposed to P

S_f = the force of the valve spring (if any)

M = the mass of the valve and half the mass of the spring

The significance of this simple equation becomes apparent when you remember that the valve is operating in a dynamic environment of constantly changing pressures in a time frame that is measured in tenths of a second. Add to that the requirement that the valve must pass a volume of fluid in each opening cycle with minimal pressure drop, and it becomes clear that the pump valve is the most critical component in the fluid end in terms of pump operability.

The pump designer will size the valves to provide a flow area, called the *spill area*, that prevents pre-established velocity limits from being exceeded. The spill area of various valve types is given in Table 10. The velocity of the fluid flowing through the spill area is called the spill velocity, V , shown in Table 11:

TABLE 10 Types of valves and their applications (Flowserve Corporation)

| TYPE | SKETCH A = SEAT AREA B = SPILL AREA | PRESSURE, PSI (BAR) | APPLICATION |
|--------|---|------------------------|---|
| PLATE |  | 5,000 (345) | CLEAN FLUID. PLATE IS METAL OR PLASTIC |
| WING |  | 10,000 (690) | CLEAN FLUIDS. CHEMICALS |
| BALL |  | 30,000 (2,069) | FLUIDS WITH PARTICLES. CLEAR, CLEAN FLUID AT HIGH PRESSURE. BALL IS CHROME PLATED |
| PLUG |  | 6,000 (414) | CHEMICALS |
| SLURRY |  | 2,500 (172) | MUD, SLURRY. POT DIMENSIONS TO API-12. POLYURETHANE OR BUNA-N INSERT |

TABLE 11 Valve spill velocities

| Valve | Spill velocity, ft/s (m/s) |
|------------------------------------|----------------------------|
| Clean liquid suction valve | 3-8 (0.9-2.4) |
| Clean liquid discharge valve | 6-20 (1.8-6) |
| Slurry suction and discharge valve | 6-12 (1.8-3.7) |

In USCS units $V \text{ (ft/sec)} = \text{gpm through the valve} \times 0.642/\text{spill area of the valve, in}^2$

In SI units $V \text{ (m/s)} = \text{m}^3/\text{h through valve} \times 555.6/\text{spill area of the valve, mm}^2$

The quantity 0.642 (555.6) is used because all the liquid passes through the valve in half the stroke.

Valve Dynamics Valve dynamics is the mechanical response of the valve to the changes of pressure across the valve. Using a suction valve as an example, the valve starts its cycle when the valve is closed and the plunger is at the start of its suction stroke (maximum insertion into the cylinder). As the plunger starts withdrawing from the cylinder, the internal volume in the cylinder starts to increase. This increasing volume results in decreasing cylinder pressure that, in turn, hydraulically unbalances the valve and the valve begins to open. There is usually a slight lag in the valve opening versus the start of the plunger motion of about 5 to 20 degrees of crankshaft rotation. Traditionally, the opening valve lag is attributed solely to the inertia required to set the valve in motion and the preload of the valve spring. In the last few years, the theory of *valve stiction* has been proposed as an additional cause of valve opening lag.

Valve stiction, as the name implies, can be an additional force to overcome when the valve is trying to lift off its seat. One version of the theory is that a cohesive force exists between the fluid molecules and the sealing surfaces of the valve and seat. This can be demonstrated by trying to separate two wet, highly machined plates. The second stiction theory focuses on possible fluid dynamic conditions that may occur as fluid starts to flow across the valve seat. Valve seats do not have “knife edge” sealing surfaces; they have a width that distributes the stresses in the valve and seat. The stiction theory postulates that the flow of fluid from the smaller area at the center of the seat to the larger area around the seat causes a pressure drop across the seat. The pressure drop is the result of the radial divergence of the fluid and is strong enough to momentarily prevent the valve from opening. Extreme cases have even resulted in a circumferential ring of cavitation located at the center of the sealing areas of the seat and valve.

Field testing valves with special grooves and radial slots in the sealing face has proven successful in reducing stiction and opening valve lag in some cases. Narrowing the sealing faces may also prove effective, although part life may decrease due to increased stress and decreased wear area. Additional computer modeling and testing is required before the stiction theory can be completely validated.

As the valve continues to open, the spill area increases proportionally. It must be remembered that fluid is now flowing through the valve at an increasing rate while trying to fill the expanding cylinder volume created by the plunger withdrawal. Ideally, the motion of the valve will exactly correspond to the flow rate of the fluid through the valve, and the valve follows a smooth trajectory to a full open position (see Figure 9).

This idyllic situation only occurs in very slow running pumps that are fitted with oversized valves. In modern higher speed pumps, the valve often accelerates at a rate fast enough to create a spill area greater than that required to maintain a constant flow velocity. At this point, the valve motion momentarily stops, and the valve may even start to close before the fluid flow once again matches the spill area. The valve then returns to the smooth trajectory until the maximum valve lift occurs.

After the plunger passes the mid point of its stroke, it starts decelerating. The flow of fluid through the valve is high enough to start to build pressure in the cylinder and unbalance the valve and start the valve closing. The valve spring has reached its maximum compression and, if properly designed, will help accelerate the valve back toward the seat. When the plunger reaches the end of the suction stroke, the valve should also be closing. The amount of crankshaft rotation that occurs between the time when the plunger reaches the end of its stroke and when the valve is completely closed is called the *delayed valve closing* and is normally 2 to 12 degrees of crank rotation. Although a delayed valve opening may have little effect on overall pump performance, a delayed valve closing certainly will. A valve that is partially open when the plunger reverses direction will result in backflow. Backflow, as the name implies, is the reverse flow of fluid back across the valve and results in lower pump volumetric efficiency.

FIGURE 9 Valve lift versus crank angle (in $\times 2.54 =$ cm)

FIGURE 10 Valve lift versus crank angle for a valve with a mechanical stop (in $\times 2.54 =$ cm)

Many pump valves are designed with mechanical limits to the distance that the valve is allowed to open or lift. This is normally done to avoid overstressing the valve spring and to minimize the overall height of the valve assembly. Valve motion for a valve designed with a mechanical stop is shown in Figure 10. Another advantage of this design is that the valve does not have to travel as far during its closing cycle, compared to valves with no mechanical limits. The disadvantage is the potential for impact damage to the valve if it strikes the stop with excessive force.

The importance of valve mass to overall valve dynamics has been the subject of much debate among pump designers over the years. There is no question that the mass of the valve must be overcome in order to open the valve. Test data is also available that shows no appreciable difference in the performance of pumps fitted with hollow ball valves versus identical pumps with solid ball valves. This apparent contradiction can be explained by studying valve acceleration at various parts of the valve cycle using advanced computer modeling.

It has already been explained above why a valve can hesitate, or stop opening, during the opening portion of its cycle. It's also been stated that when the valve spill area is large enough to establish a hydraulic balance, the valve will stop opening. What actually occurs is the valve starts decelerating as it comes closer to hydraulic equilibrium. If the valve is properly designed, it will contact its mechanical stop just as its acceleration/deceleration is very low. In that case, the valve mass has little significance on the impact force of the valve on the stop. The same holds true of the impact force of the valve on the seat as it closes. If the valve is properly designed, a 62-lb (28 kg) solid ball valve operating at 100 cycles per minute can strike the seat with less than 20 lbs (9 kg) of force.

Although pump valves operate in a liquid medium, the shape of the valve is not an important design consideration for most applications. The relatively small distance that a valve travels is not sufficient for the fluid dynamics of a shape to have a measurable effect on valve dynamics. The only exception to this is valves in pumps handling high-viscosity liquids. For these applications, the ball valve, often spring-loaded, has proven to reduce closing valve lag and increase volumetric efficiency better than any other type of valve.

The most critical component in the optimization of valve dynamics is the valve spring. The pump designer normally selects a valve spring that will exert a certain amount of "pre-load" on the valve when it is closed. This pre-load helps the valve to close smoothly on the seat and avoid rebound (and possible backflow). Too high a preload in the suction valve may result in higher net positive suction head required (NPSHR). In the discharge valve, excessive preload can cause abnormally high pressure spikes in the fluid cylinder just before the valve opens.

The other valve spring design criterion is the spring rate. Every compression spring develops a predetermined resistance per unit length. This value is expressed in pounds per inch (kg per cm). As the valve is opening, the increasing spring force helps the valve obtain hydraulic balance faster. It also helps to limit the impact force of the valve on the stop. At the start of the closing cycle, the stored energy in the compressed spring helps the valve respond faster to the pressure changes in the fluid cylinder as the plunger starts to decelerate. Again, if the spring is properly designed, the closing valve lag will be minimized.

No published guidelines exist for the proper amount of valve spring pre-load or spring rate. Most pump designers use proprietary values, generated through a combination of in-house and field testing. However, although these values produce low NPSHR and high volumetric efficiency in most cases, the valve dynamics may not be close to being optimized. It should also come as no surprise that pumps fitted with "off-the-shelf" commercially available valves do not operate as well as pumps having optimized valve dynamics.

With the recent advent of advanced computer modeling of pump valves, it is now possible to optimize valve dynamics for a specific set of pump operating parameters. We may also see valve designs in the near future having variable rate valve springs, hydraulic dampening, and mechanisms that induce rotation as the valve opens and closes.

POWER END THEORY

The power end or drive end of a power pump consists of a crankshaft, connecting rods, crossheads, and bearings, all housed in a rigid structure referred to as the frame. Details of the design and construction of these components are covered in Section 3.2, "Power Pump Design and Construction." The slider-crank mechanism that converts rotational driving energy to the reciprocating motion that actuates the pistons or plungers can be found in reciprocating gas compressors, automotive engines, and stationary and marine engines. However, the stress loading pattern of power pump components is unique to this type of mechanism.

FIGURE 11 Power end, horizontal pump (Flowserve Corporation)

FIGURE 12 Power end, vertical pump (Flowserve Corporation)

Applying Rod Load to the Power End As stated earlier, the loading on the power end is called the rod load and is the product of the area of the plunger multiplied by the maximum discharge pressure. In a gas compressor or engine, this loading increases over 90 to 180 degrees of crank rotation before maximum loading is reached. In a power pump, the maximum loading is reached in less than 30 degrees of crank rotation due to the relative incompressibility of the pumpage. Since this loading cycle is repeated with each plunger stroke, the actual loading resembles a shock load more than a simple cyclic fatigue load. The design criteria for the stressed components of the power end must therefore include the material's capability to absorb shock loads and overall safety factors greater than 3:1.

Another critical factor in the capability of the power-end components to handle the rod load is how the load is applied. Figures 11 and 12 show the direction of the load on the

frame and connecting rod for two different power end configurations. On vertical pumps with outboard packed stuffing boxes, the frame is in compression and the crosshead and connection rod are in tension. With horizontal, single-acting pumps, the frame is in tension, and the crosshead and connecting rod are in compression. The material selection and factors of safety must be altered accordingly.

Liquid Separation from the Plunger It has already been explained that fluid flows through the suction valve (and suction manifold and related piping) to fill the increasing cylinder volume caused by the withdrawal of the plunger. If the plunger accelerates faster than the flow of incoming liquid, the liquid will lose contact or separate from the plunger. The void that forms will be at a pressure lower than anywhere else in the cylinder. If the pumpage contains entrained gas, the gas may come out of a solution in this low-pressure area. The gas bubbles, when recompressed later in the plunger stroke, can cause cavitation damage to the plunger and surrounding cylinder.

The geometry of the slider-crank mechanism affects the point at which liquid separation occurs. As the ratio of the connecting rod length to the crank radius increases, the pump speed at which liquid separation occurs will decrease. Since liquid separation can be the determining factor in a pump's NPSHR, the pump designer must carefully evaluate the slider-crank geometry in order to optimize the pump's hydraulic performance. The pump speed at which water will separate from the end of the plunger can be calculated from the following:

$$\text{In USCS units:} \quad \text{rpm} = 54.5 \sqrt{\frac{(34 - h_s - h_f)A_s}{LR[l - (l/LR)]A_p}}$$

$$\text{In SI units:} \quad \text{rpm} = 16.6 \sqrt{\frac{(10.36 - h_s - h_f)A_s}{LR[l - (l/LR)]A_p}}$$

where h_s = suction head, ft (m)

h_f = piping frictional loss, ft (m)

A_s = area of suction pipe, in² (mm²)

L = length of connecting rod, centerline to centerline, ft (m)

R = crank radius, ft (m)

l = length of pipe where resistance to flow is to be measured, ft (m)

A_p = area of plunger, in² (mm²)

Unbalanced Forces Due to the relatively slow speed of a power pump, the inertia loads of the rotating/reciprocating parts are low enough to avoid the vibration problems associated with centrifugal pumps. For that reason, power pump crankshafts are not normally balanced. However, when the power pump is coupled to a drive containing a high-speed motor and gear reducer, a torsional analysis of the pump/drive unit may be required. For this analysis, the unbalanced forces of the rotating and reciprocating pump components can be calculated as follows:

Unbalanced Reciprocating Parts Force (F_{rec}) Parts are typically about one-third of the connecting rod weight (the crosshead, the crosshead bearing, the wrist pin, the pony rod, and the plunger). Additional parts on vertical pumps include the pull rods, yoke, and plunger nut.

$$F_{rec} = \frac{W}{g} \omega^2 R \left(\cos \theta + \frac{R}{L} \cos \theta \right)$$

where F_{rec} = reciprocating parts force, lb (N)

W = weight of all reciprocating or rotating parts, lb (N)

$$g = 32.2 \text{ ft/s}^2 (9.81 \text{ m/s}^2)$$

$$\omega = (2\pi/60) \times n \text{ (n = pump rpm)}$$

$$R = \text{one-half of stroke, ft (m)}$$

$$L = \text{length of connecting rod, centerline to centerline, ft (m)}$$

$$\theta = \text{crank angle; usually maximum force is at } \theta = 0^\circ, \cos \theta = 1$$

Unbalanced Rotating Parts Force (F_{rot}) Parts are typically about two-thirds of the connecting rod weight, crank end bearing, and crankpin, where the variables are as above.

$$F_{rot} = \frac{W}{g} \omega^2 R$$

Mechanical Efficiency The mechanical efficiency of a single-acting power pump without internal gears is typically 90 to 92%. Over half of the mechanical losses are due to the frictional drag of the plungers through the packing. The remaining losses are from the bearings, the crosshead-to-crosshead guide friction, and the extension rod-to-gland seal friction. If these components are properly lubricated, very few power-end design options are available that will produce a measurable increase in mechanical efficiency. Decreasing the diameter of the plungers and minimizing the number of packing rings will result in a small efficiency increase.

SECTION 3.2

POWER PUMP DESIGN AND CONSTRUCTION

WILLIAM K. CHAPLIS
FREDERIC W. BUSE

The power pump, as a piece of rotating equipment, would seem to have a great deal in common with a reciprocating gas compressor or diesel or gas engine. All have crankshafts, bearings, connecting rods, and lubricating oil systems that use the pump frame as an oil reservoir. All have a fluid or gas end that contains relatively high pressure and includes some type of valving that enables the equipment to perform its required task.

Due to the unique operating characteristics of the power pump, very little design criteria or construction details can be directly transferred from these other mechanisms. Because of the high compressibility of most gases, the resulting cyclic loadings are applied to the various rotating, reciprocating, and pressure-retaining components in a smoother manner. Therefore, gas-driven or gas-pumping mechanisms can operate at speeds three or four times higher than a reciprocating pump with good reliability and low vibration levels.

It has been said that a power pump has more in common with a jackhammer because of the constant high-cycle shock loading that it must be designed to withstand. Therefore, very conservative material selections, stress limits, and factors of safety have been established by the pump designers for all continuous duty applications. Intermittent duty applications can be met using less stringent design criteria.

Seldom is a power pump designed for one specific application having one specific set of operating conditions. Consequently, few pump designs are truly optimized. The best economical approach has been to design a power end capable of accepting a number of fluid ends, which in turn allows the pump to operate over a wide range of hydraulic conditions. By using different plunger diameters for a specific operating pressure, the designer tries to "load up" the power to its maximum continuous rod load rating while maintaining the pump speed at a level just sufficient to provide the required flow rate.

A power pump has its cylinders operating in parallel with interconnecting suction and discharge manifolds. Additional cylinders are sometimes added to a basic power-end design in order to obtain higher flow rates. The most common examples of this approach are the quintuplex pumps that have an 80-percent component interchangeability with

triplex pumps. Triplex (three cylinder), quintuplex (five cylinder), septuplex (seven cylinder), and nonoplex (nine cylinder) pumps have been designed that have over a 90-percent interchangeability of parts. Only the power frame and crankshaft are unique to a specific pump size.

Factors of safety are used in power pump design and application. A connecting rod assembly, for instance, normally has a safety factor in excess of a 3:1 ratio because if a connecting rod fails in operation, it normally destroys many other power-end parts. A nodular iron frame will have a high safety factor also, primarily due to the requirement for thick wall sections to mount interfacing parts and to reduce operating noise levels. Some fluid-end expandable parts in the stuffing box and valves have safety factors below a 1.5:1 ratio because these parts are normally replaced before they would fail due to fatigue.

There has been a trend in past years in most industries to purchase power pumps that operate at higher and higher speeds. This has been driven by the economics of buying smaller, higher speed equipment versus the older, large, slower speed pumps. This trend seems to be losing some momentum, especially in critical applications. It remains for the pump purchaser and pump supplier to jointly evaluate each application and try to arrive at a pump selection that will provide the most reliable performance for the lowest installed cost and operating cost.

LIQUID END

The liquid end consists of the cylinder, the plunger or piston, the valves, the stuffing box, the manifolds, and the access covers. Figure 1 shows the liquid end of a horizontal pump, and Figure 2 shows the same for a vertical pump.

Cylinder (Working Barrel) The cylinder is the body where the pump pressure to overcome discharge pressure is developed. It is continuously under fatigue. Cylinders on many horizontal pumps have suction and discharge manifolds integral with the cylinder. Vertical pumps have separate manifolds.

A cylinder containing the passages for more than one plunger is referred to as a *single cylinder*. When the cylinder is used for one plunger, it is called an *individual cylinder*. Individual cylinders are used where developed stresses or replacement costs are high.

Cast cylinders are usually limited to the developed pressures listed in Table 1. Forged cylinders are made from 1020 and 4140 carbon steel; 304L, 316L, 17-4 PH, and 15-5 PH stainless steels; and nickel aluminum bronze. In recent years, duplex stainless steels have seen an increase in usage when higher strength and corrosion resistance is required.

FIGURE 1 A liquid-end horizontal pump (Flowserve Corporation)

FIGURE 2 A liquid-end vertical pump (Flowserve Corporation)

TABLE 1 Maximum pressure in cast cylinders

| Material | lb/in ² (bar) |
|-----------------|---------------------------|
| Cast iron | 2000 (137) |
| Aluminum bronze | 2500 to 3000 (172 to 207) |
| Steel | 3000 (207) |
| Ductile iron | 3000 (207) |

Forged cylinders have a 4:1 to 6:1 forging reduction on all sides of the cylinder to obtain a homogeneous internal structure. This type of cylinder requires heat treatment after forging to eliminate the stresses that occur during the forming operation. The pump designer must minimize the section thickness of the cylinder or residual stresses may remain after machining the internal bores.

The highest stresses occur at the intersection of the horizontal and vertical internal bores. Unlike a simple cylinder where the internal stresses are analyzed as a single hoop stress, the stress at the intersecting bores of a power pump cylinder are based on a double hoop stress. In Figures 3 and 4, the distances b and d are the internal diameters, a and c are the diameters to the nearest obstruction of the solid material of the cylinder, P is the developed pressure, and S is the resulting stress. Stress concentration factors at the intersecting bores can be omitted if the radius is not less than 0.25 in (1.5 mm). Above 3000 lb/in² (207 bar), the internal bores should have a surface finish of 63 rms minimum.

During each plunger cycle, the developed pressure goes from suction pressure to discharge pressure and back to suction. For a pump operating at 360 strokes per minute, over six million fatigue cycles will occur in less than 12 days. For this reason, very conservative allowable stress limits are used. Normally, these limits range from 10,000 to 25,000 lb/in² (69 to 172 Mpa), depending on the material of the cylinder, duty cycle, and liquid being

FIGURE 3 Stress dimensions for a horizontal liquid end (Flowserve Corporation)

$$S = P \left[\left(\frac{a^2 + b^2}{c^2 - b^2} \right) + \left(\frac{c^2 + d^2}{c^2 - d^2} \right) \right]$$

FIGURE 4 Stress dimensions for a vertical liquid end (Flowserve Corporation)

pumped. The allowable stress is a function of the fatigue stress of the material for the liquid being pumped and the life cycles required.

Due to improper suction system design, misapplications, or process upsets, instantaneous pressure in the cylinder may be much higher than design pressure. When the liquid contains entrained gas that can be released because of inadequate suction pressure, the resulting cavitation can cause instantaneous pressure four to five times the design pressure. This results in reducing the life of the cylinder and other liquid-end components, as well as damaging pressure pulsations in the suction and discharge piping systems.

For continuous duty pumps operating above 10,000 lb/in² (690 bar) of discharge pressure, special liquid-end designs have been developed. In Figure 5, the intersecting bores have been eliminated by arranging the suction and discharge valves on the same axis as the plunger. This means the stresses in the cylinder will be only half of those in a comparable T-block design.

Plungers The plunger transmits the force that develops the pressure. It is normally a solid construction of up to 5 in (127 mm) in diameter. Above that dimension, it may be made hollow to reduce its weight. Small-diameter plungers used for 6000 psi (414 bar) and above should be reviewed for possible buckling. Plunger speeds range from 150 to 350 fpm (46 to 107 m/s). The surface finish normally is between 14 and 20 rms. A finish below 8 rms should be avoided because excessive packing leakage may occur due to the inability of the packing to seal properly on the smooth surface.

Although some plungers are made of heat-treated or case-hardened steel, the most common are the hard-coated or solid ceramic. The hard coatings are normally flame sprayed powders of Colmonoy or tungsten carbide, or ceramic oxides. These can be applied over base materials of 1020 carbon steel or 316L stainless steel. Ceramic oxide is normally limited to 200°F (93°C) and is used for soft water, crude oil, mild acids, and mild alkalis.

The porosity and bond strength of coatings must be carefully evaluated for use with higher operating pressures. Under those conditions, the liquid may penetrate the pores of the coating and lift the coating off the base material. Ceramic plungers also have special requirements and limitations. This type of plunger is often constructed as a solid bar, closed-end tube of ceramic, bonded to a metal end cap or plug. A vent must be provided to allow the pressure inside the plunger to equal the atmospheric pressure or the ceramic-to-metal bond may fail or the plunger may explode. In addition to the normally fragile nature of any ceramic plunger, the solid ceramic plunger is susceptible to failure due to thermal shock.

Pistons Pistons are used for water pressures up to 2000 lb/in² (138 bar). For higher pressures, a plunger is usually used. Pistons are cast iron, bronze, or steel with reinforced elastomer sealing rings (see Figure 6). They are most frequently used in duplex, double-acting pumps. The latest trend is to use pistons in single-acting triplex pumps.

FIGURE 5 Special high-pressure liquid-end designs arrange the suction and discharge valves on the same axis as the plunger, thus eliminating intersecting bores (Flowserve Corporation).

FIGURE 6 Elastomer face piston (FWI)

Stuffing Box The stuffing box assembly consists of a stuffing box, upper and lower bushings, packing, and a gland. For ease of maintenance, the stuffing box assembly is usually removable (see Figure 7).

The stuffing box bore is machined to a 63 rms finish to ensure packing sealing and life. A single hoop stress equation is used to determine the wall thickness with an allowable stress limit of 10,000 to 20,000 lb/in² (69 to 138 MPa).

The bushings that guide the plunger have a 63 rms finish with approximately 0.001 to 0.002 in (0.02 to 0.05 mm) of diametrical clearance per inch of the plunger diameter. The

FIGURE 7 A stuffing box (Flowserve Corporation)

FIGURE 8 Chevron packing (Flowserve Corporation)

FIGURE 9 Single-acting piston stuffing box (Flowserve Corporation)

lower bushing is sometimes secured in an axial position to prevent movement of the packing. Bushings are made of bearing bronze, Ni-resist, or cast iron. Stainless steel can be used if its antigalling properties with the plunger coating can be verified.

Packing is either square cross-section, woven construction or molded V or chevron-shaped (see Figure 8). Some types use metal backup adapters. A packing set consists of top and bottom adapters and one or more packing sealing rings. A stuffing box can use two to five rings of packing, depending on the pressure and the fluid being pumped. Packing rings are usually made up of a number of composite materials selected for their strength, wear resistance, and lubricity, including neoprene, Teflon, cotton duct, and Kevlar.

Packing can be made self-adjusting by installing a spring between the bottom of the packing set and the lower bushing or bottom of the stuffing box. This arrangement eliminates overtightening the packing and enables a more uniform break-in. Packing can be lubricated through a grease fitting or by an auxiliary lubricator driven through a take-off on the crankshaft.

For chemical or slurry service, a lower injection ring is used for flushing. This prevents concentrated pumped fluid from impinging directly on the packing. This injection can be continuous or synchronized to inject only on the suction stroke. Flush glands at the outboard end of the stuffing box are employed when a toxic vapor is present or when the leakage may flash.

The stuffing box for the piston rod of a double-acting pump is similar in construction to that of a stuffing box for a plunger. The primary difference is that it must seal against pressure being developed while the rod moves back through the packing. Single-acting pistons do not employ a stuffing box. Leakage past the piston-sealing rings goes into the frame extension to mix with the continuously circulating lubricant.

Cylinder Liner The cylinder wear liner (refer to Figure 6 and see Figure 9) is usually of Ni-resist material. Its length is slightly longer than the stroke of the pump to enable an assembly entrance taper of the piston into the liner. In double-acting pumps, the liner has packing to prevent leakage from the high-pressure side to the low pressure side of the

cylinder. Because of the brittleness of the liner, the construction should be such that the liner is not compressed. The finish of the bore of the liner is approximately 16 rms.

Valves Many types of valve designs exist. Which type is used depends on the application. The main parts of a valve assembly are the seat and sealing member, usually a disc, ball, or plate. The plate movement is controlled by a spring or retainer. The seat usually uses a taper where it fits into the cylinder or manifold. The taper not only gives a positive fit but permits easy replacement of the seat.

Some pumps use the same size suction and discharge valve for interchangeability (refer to Figure 2). Some use larger suction valves than discharge valves for improved NPSH reasons. Others use larger discharge valves than suction valves because the cylinder configuration requires the suction valve to be removed through the location of the discharge valve (refer to Figure 1). Because of space considerations, valves are sometimes used in clusters on each side of the plunger to obtain the required total valve area that reduces valve velocity.

Table 2 shows seat and plate hardness for some valve materials. Seats and plates made of 316 stainless steel material are usually chrome-plated or flame-sprayed to give them the desired surface hardness.

The flow area of the valve must be large enough to prevent significant pressure drop or restriction to flow. Normally, suction valves are sized for 6 to 8 ft/s velocity, and the discharge valves are sized for 8 to 12 ft/s.

The valve springs must be made of corrosion-resistant material and designed to withstand high-cycle fatigue stresses. Under no situation should the valve operation enable the spring to go to a solid stack height or wire-to-wire condition. The ends of the spring must be ground flat and square with a maximum perpendicularity of 3 degrees.

Manifolds These are the chambers where the liquid is disbursed or collected for distribution before or after passing through the cylinder. In horizontal pumps and some vertical pumps, the manifolds are cast or machined integral with the fluid cylinder. Most vertical pumps have the suction and discharge manifolds separate from the cylinder (refer to Figure 2).

Suction manifolds are designed to eliminate air pockets from the flange to the valve entrance (see Figure 10). Separate suction manifolds are cast iron, cast bronze, or fabricated steel. Discharge manifolds are steel forgings or fabricated steel. The manifolds have a minimum deflection to prevent gasket shifts when subjected to maximum operating pressures.

The velocity through the manifolds of a clean liquid is 3 to 5 ft/s (0.9 to 1.5 m/s) at the suction and 6 to 16 ft/s (1.8 to 4.9 m/s) at the discharge. Suction and discharge manifold velocities in a slurry service are 6 to 10 ft/s (1.8 to 3 m/s). Slurry services have a minimum velocity of 6 ft/s (1.8 m/s) to prevent the heavier slurry particles from falling out of solution.

In USCS units, $V \text{ (ft/s)} = \text{pump gpm} \times 0.321 / \text{cross-sectional area of the manifold, in}^2$

In SI units, $V \text{ (m/s)} = \text{pump m}^3/\text{h} \times 277.8 / \text{cross-sectional area of the manifold, mm}^2$

TABLE 2 Recommended material hardness for valve plate and seat

| Material | Plate | Seat |
|----------------------------|------------|------------|
| Rockwell C hardness | | |
| 329 | 30 to 35 | 38 to 43 |
| 440 | 44 to 48 | 52 to 56 |
| 17-4 PH | 35 to 40 | 40 to 45 |
| 15-5 PH | 35 to 40 | 40 to 45 |
| Brinell hardness | | |
| 316 | 150 to 180 | 150 to 180 |

FIGURE 10 A suction manifold construction to eliminate air pockets (Flowserve Corporation)

FIGURE 11 An integral suction and discharge manifold (Gardner-Denver)

A water hammer creates an additional pressure (which is added to the rated pump pressure), as does hydraulic shock loading. The discharge manifold rating is then made equal to or greater than the sum of these pressures.

Valve Covers Valve covers are used to provide accessibility to the valves without disturbing the cylinder, manifold, or related piping (see Figures 11 and 12).

Plunger Covers and/or Cylinder Heads These are used on horizontal pumps to provide accessibility to the plunger, piston, and cylinder liner (refer to Figures 11 and 12 and see Figure 13).

POWER END

The power end contains the crankshaft, connecting rods, crossheads, pony rod, bearings, and frame (see Figures 14 and 15). Basic designs are horizontal and vertical with sleeve or antifriction bearings. Some have integral drive gears.

Frame The frame absorbs the plunger load and torque. Vertical pumps with outboard packed stuffing boxes (refer to Figure 2) have the frame in compression (refer to Figure 14). With horizontal single-acting pumps, the frame is in tension (refer to Figure 15). Frames are usually close-grain cast iron with relatively thick cross-sections. This combination provides superior dampening for the normal low-frequency cyclic loading. Some intermittent duty pumps, specifically designed for mobile services, are constructed of lighter weight, fabricated steel plate.

The frame is usually vented to the atmosphere. However, when the atmosphere is detrimental to the working parts of the frame, such as an ammonia attack on bronze bearings, the frame can be purged continuously with nitrogen gas.

Crankshaft The crankshaft (see Figures 16, 17, and 18) varies in construction, depending on the design and power output of the pump. In horizontal pumps, the crankshafts are usually of nodular iron or cast steel. Vertical pumps use forged steel or machined billet crankshafts. Because the crankshafts have a low mass and operate at relatively low

FIGURE 12 Separate suction with an integral discharge manifold (Gardner-Denver)

FIGURE 13 A plunger cover (FWI)

FIGURE 14 A vertical pump power end (Flowserve Corporation)

speeds, counterweights and flywheels are not used. Except for duplex pumps, the crankshaft always has an odd number of throws to obtain the best flow pulsation characteristics. The firing order in a revolution depends on the number of throws on the crankshaft (see Table 3).

The crankshaft main and rod-bearing surfaces are ground to a 16 rms surface finish or better. Large radii are used where journal diameters intersect with the adjacent cheeks to

FIGURE 15 A horizontal pump power end (Flowserve Corporation)

**FIGURE 19** The connecting rod (Flowserve Corporation)

minimize stress concentrations in these fatigue-prone areas. Cross-drilling of the main to rod journals is often provided to furnish lubrication to the crankpin bearings.

Many horizontal pumps under 250 hp (186 kW) are driven by means of a sheave or pulley and belt arrangement. Increasing the diameter of the pulley for a given horsepower will increase the stress in the crankshaft. The maximum allowable crankshaft stress will often limit the maximum diameter of the pulley that can be used. Stress levels of 2000 to 3000 lb/in² (14 to 20.7 MPa) are common, where d is the pulley end diameter of the crankshaft in inches (mm) and n is the pump speed in revolutions per minute.

Connecting Rods and Eccentric Straps The connecting rods (see Figure 19) transfer the rotating force of the crank pin to an oscillating force on the wrist pin. Most connecting rods are split perpendicular to their centerline at the crankpin end for ease of assembly onto the crankshaft.

The cap and rod are aligned with close-tolerance bushings or body-bound bolts. The rods either are rifle-drilled or have cast passages to transfer oil from the wrist pin to the crank pin. A connecting rod with a tension load is made of forged steel, cast steel, or fabricated steel. Rods with a compressive loading are cast steel, nodular iron, or aluminum alloy. The connecting rod finish, where the bearings are mounted, is 32 to 63 rms.

The ratio of the distance between the centerlines of the wrist pin and crank pin bearings to half the length of the stroke is referred to as the L/R . The ratio directly affects the pressure pulsations, volumetric efficiency, size of the pulsation dampener, speed of liquid separation, acceleration head, moments of inertia forces, and size of the frame. Low L/R results in higher fluid pulsations. A high L/R reduces pulsations but may result in a large and uneconomical power frame. The common industrial L/R range is 4:1 to 6:1.

The eccentric strap (see Figure 20) performs the same function as a connecting rod, except that the former usually is not split. The eccentric strap is furnished with rolling element bearings, whereas connecting rods are furnished with sleeve bearings. Eccentric straps are applied to mud pumps and some slurry pumps, which are started against a full load without requiring a bypass line.

Wrist Pin Located in the crosshead, the wrist pin transforms the oscillating motion of the connecting rod to a reciprocating motion. The maximum stress in the wrist pin from deflection should not exceed 10,000 lb/in² (69 MPa):

FIGURE 20 An eccentric strap (Gardner-Denver)

FIGURE 21 A crosshead (Gardner-Denver)

FIGURE 22 Crossways (Gardner-Denver)

In USCS units,

$$S = \frac{PL \times \ell}{8 \times 0.098d^3}$$

In SI units,

$$S = 1.25 \frac{PL \times \ell}{d^3}$$

where PL = plunger load, lb (N)

ℓ = length under load, in (mm)

d = diameter of pin, in (mm)

Large pins are hollow to reduce the oscillating mass and assembly weight. Depending on the design, pins can have a straight fit, taper fit, or loose fit in the crosshead. The pin is case-hardened and has a surface finish of 16 rms or better. When needle or roller bearings are used for the wrist pin bearing, the pin serves as the inner race.

Crosshead The crosshead (see Figure 21) moves in a reciprocating motion and transfers the plunger load to the wrist pin. The crosshead is designed to absorb the side or radial load from the plunger as the crosshead moves linearly on the crossway. The side load is approximately 25% of the plunger load. For cast-iron crossheads, the allowable bearing load is 80 to 125 lb/in² (551 to 862 kPa). Crossheads are grooved for oil lubrication and have a 63 rms surface finish. Crossheads are piston types (full round) or partial-contact types. The piston type should be open or vented to prevent air compression at the end of the stroke.

In vertical pumps, the pull rods, or side rods, go through the crosshead so that the crosshead is under compression when the plunger load is applied (refer to Figure 14).

Crosshead Guides (Crossways) The crossway (see Figure 22) is the surface on which the crosshead reciprocates. In horizontal pumps, it is cast integral with the frame (refer to Figure 15). In large frames, it is usually replaceable and is shimmed to effect proper running clearances (refer to Figures 14 and 22). The crossway finish is 63 rms.

Pony Rod (Intermediate Rod or Extension Rod) The pony rod is an extension of the crosshead on horizontal pumps (refer to Figures 21 and 22). It is screwed or bolted to the

crosshead and extends through the frame (refer to Figure 15). A seal on the frame and against the pony rod prevents oil from leaking out of the frame. A baffle is attached to the plunger end of the pony rod to prevent stuffing box leakage from entering the frame.

Pull Rod (Side Rod) In vertical pumps, two pull rods are connected to the crosshead. The rods are secured by a shoulder and nut so that the cast iron is in compression when the plunger load (rod load) is applied. The rods extend out through the top of the frame and fasten to a yoke (upper crosshead). The plunger is attached to the middle of the yoke with an aligning feature for the plunger (refer to Figure 2). The nuts fastening the pull rod to the yoke and crosshead must be torqued to a high enough level to prevent the bolted joint from seeing cyclic loading.

Bearings Both sleeve and rolling element bearings are used in power pumps. Some power ends use all sleeve, others use all rolling element, and others use a combination of both.

SLEEVE BEARINGS

When properly installed and lubricated, sleeve bearings are considered to have an infinite life. They are inexpensive and can usually be replaced without special tools and with minimum pump disassembly. The sleeve bearing is designed to operate within a certain speed range, and too high or too low a speed will upset the oil film lubrication. With standard sleeve-bearing designs, pumps cannot be operated at speeds below 20 rpm with the plunger fully loaded using standard lubrication. Below this speed, the oil film in the wrist pin bearing starts to break down and the increased friction causes excessive heat and leads to bearing failures. Recent developments of improved bearing materials, along with special grooving and other aids to lubrication, now allow for fully loaded pump operations at speeds as low as 10 rpm. The finish on the sleeve bearing is 16 rms. Clearances are approximately 0.001 in per in (0.001 mm per mm) of the diameter of the bearing.

Wrist Pin Bearings These bearings are normally the highest loaded bearings in the pump. They can only perform an oscillating motion and therefore cannot develop the dynamic oil film common to fully rotational bearings. In single-acting pumps with low suction pressure, adequate reversals in loading take place on the bearing to permit replenishment of the oil film. High suction pressure in a horizontal pump increases the reverse loading. In vertical pumps, high suction pressure can produce a condition of no reverse loading, and in this case, special bearing materials, grooving, and pump derating may be required. Increasing oil pressure by itself will not solve this problem. Allowable projected area loading is 1200 to 1500 lb/in² (8.27 to 10.3 MPa) with bearing bronze.

Crank Pin Bearings The crank pin bearing is a rotating split bearing and develops a better oil film than the wrist pin bearing. It is clamped between the connecting rod and cap. The bearing is a bronze-backed babbitt metal or a tri-metal automotive type bearing. The allowable projected area load is 1200 to 1600 lb/in² (8.27 to 11.08 MPa).

Main Bearings The main bearings absorb the plunger load and gear load. The total plunger load varies during each revolution of the crankshaft. The triplex main bearings receive the greatest variations in loading because the crankshaft has the greatest relative span between bearings. Sleeve bearings are flanged to locate them in an axial position, and the flange absorbs residual axial thrust. In long-stroke vertical pumps, a main bearing can be found between every connecting rod. Split bearings are a bronze-backed babbitt metal with an allowable loaded area of 750 lb/in² (5.1 MPa).

ROLLING ELEMENT BEARINGS

A pump with rolling element bearings can be started under a full plunger load without a bypass line. Rolling element bearings enable the pump to operate continuously at low speeds with full plunger loads. They are selected for 30,000 to 50,000 hours of L_{10h} life. Slurry pipeline applications may require 100,000 hours. Eccentric straps are used in place of connecting rods.

Wrist Pin Bearings These are needle or roller bearings. The outer race is a tight fit into the strap, and the wrist pin is used as the inner race. This reduces the size of the bearing and strap. The wrist pin is held in the crosshead with a taper or keeper plate (see Figure 23).

Main Bearing The main bearings used in conjunction with sleeve wrist pin bearings and sleeve crank pin bearings are usually tapered roller bearings, as is the case with a horizontal triplex plunger pump. The main bearings are usually mounted directly into the frame (see Figure 24).

The main bearings used with full rolling element bearing designs are self-aligning spherical roller bearings. These bearings compensate for axial and radial movements of the crankshaft and are usually mounted in bearing holders, which in turn are mounted on the frame (refer to Figure 23). This type of design is mostly used in mud pumps and in some slurry pumps.

LUBRICATION

Non-detergent SAE 30 to 50 oil is used for bearing lubrication. In splash lubrication, the cheeks of the crankshaft or oil scoops (refer to Figure 15) throw oil by centrifugal force against the frame wall. This oil is then distributed by gravity to the crosshead, wrist pin, and crank pin. At low speeds, there is not enough centrifugal force for proper oil distribution, so a partial force feed is then employed to maintain proper lubrication. Force-feed lubrication requires 0.5 to 1 gpm (1.9 to 3.8 l/m) per bearing with an oil pressure of 28 to 40 lb/in² (1.7 to 2.8 bar).

APPLICATIONS

Power pumps are used in a variety of applications where high-pressure and low-flow requirements exist. They are also widely used when a high-volumetric efficiency is

FIGURE 23 The main bearing mounted in a bearing holder (Gardner-Denver)

FIGURE 24 The main bearing mounted directly in the frame (Flowserve Corporation)

required. For these applications, other types of pumps have design or operating deficiencies that make their lower initial cost or lower maintenance costs less attractive.

Some of the common applications for power pumps include the following:

| | |
|-----------------------------|--|
| Ammonia service | Liquid petroleum gas |
| Carbamate service | Liquid pipeline |
| Chemicals | Power oil |
| Crude-oil pipeline | Power press |
| Cryogenic service | Salt-water injection for water flood |
| Fertilizer plants | Slurry pipeline (up to 70 percent by weight) |
| High-pressure water cutting | Slush ash service |
| Hydro forming | Steel mill descaling |
| Hydrostatic testing | Water blast service |

The following applications may require power pumps with special modifications, and the exact requirements should be reviewed in detail with the pump supplier:

| | |
|-----------------------------|-----------------------------|
| Cryogenic service | Low-speed operation |
| Highly compressible liquids | Slurry pipeline |
| Liquids over 250°F (121°C) | Special fluid-end materials |
| Liquids with entrained gas | Viscosities over 500 SSU |

Duty Service To make an economical pump selection, the type of full-load service that you need should be considered. For instance, a small, lighter weight pump operating at higher speeds may be suitable for an intermittent duty application such as hydrostatic testing. The different types of duty services are as follows:

- *Continuous*: 8 to 24 hours per day
- *Light*: 3 to 8 hours per day
- *Intermittent*: Up to 3 hours per day
- *Cyclic*: 30 seconds loaded out of every 3 minutes

RELIEF VALVES

Relief valves should be rated for the full flow of the pump. The *set pressure* or *cracking pressure* must be sufficiently above the operating pressure to prevent normal pressure pulsations from activating the relief valve. The following values can be used as guidelines, but the final selection should be made only in agreement with the pump supplier and system designer:

- Duplex double-acting: 25 percent
- Triplex and above: 10 percent

Bypass Relief Starting a power pump under a full load requires a high starting torque. Also, a pump with sleeve-bearing construction when starting under a full load may not have adequate bearing lubrication to reach the operating speed.

The starting torque on the driver and plunger load on the bearings may be reduced by performing one of two steps:

- Install a bypass line from the discharge back to the source or to a drain (see Figure 25). This line is located between the pump discharge and a check valve before the discharge piping system. The bypass valve is operated manually or automatically. The bypass line

FIGURE 25 A bypass relief system (Flowserve Corporation)

reduces the starting torque from the mechanical losses and the liquid inertia of the suction and bypass systems. After the pump is up to speed, the bypass is closed and the pump goes into normal operation.

- Use suction valve unloaders. The unloader is a mechanism that mechanically holds the suction valves off of their seats before and during startup, which stops the pumping action. Only mechanical losses must be overcome. After the pump is up to speed, the suction valves are closed in unison. In large-flow pumps, an electronic distributor is used to synchronize actuation of the suction valves with the plunger pressure build-up order (or firing order).

PULSATION DAMPENERS

The performance of a power pump, or its interaction with the suction and discharge piping systems, can often be improved by adding suction and discharge dampeners. Dampeners are used to reduce suction and discharge pressure pulsations. A properly sized and located suction dampener can reduce the system pulsations to an equivalent pipe length of 5 to 15 pipe diameters. If the dampener is the flow-through type, it should be located on the same side as the pipe, not at the dead end of the manifold.

The most commonly used dampeners are the gas-bladder types. These units are normally charged with nitrogen gas at 50 to 66 percent of the system pressure. Although these units are relatively inexpensive, they can attenuate up to 90 percent of the pressure pulsations, below 50 Hz, in the interconnecting piping systems.

SECTION 3.3

STEAM PUMPS

ROBERT M. FREEBOROUGH

BASIC THEORY

A reciprocating positive displacement pump is one in which a plunger or piston displaces a given volume of fluid for each stroke. The basic principle of a reciprocating pump is that a solid will displace an equal volume of liquid. For example, when an ice cube is dropped into a glass of water, the volume of water that spills out of the glass is equal to the submerged volume of the ice cube.

In Figure 1, a cylindrical solid, a plunger, has displaced its volume from the large container to the small container. The volume of the displaced fluid (B) is equal to the plunger volume (A). The volume of the displaced fluid equals the product of the cross-sectional area of the plunger and the depth of submergence.

All reciprocating pumps have a fluid-handling portion, commonly called the *liquid end*, that has

1. A displacing solid called a *plunger* or *piston*
2. A container to hold the liquid, called the *liquid cylinder*
3. A suction check valve to admit fluid from the suction pipe into the liquid cylinder
4. A discharge check valve to admit flow from the liquid cylinder into the discharge pipe
5. Packing to seal the joint between the plunger and the liquid cylinder tightly to prevent liquid from leaking out of the cylinder and air from leaking into the cylinder

These basic components are identified on the rudimentary liquid cylinder illustrated in Figure 2. To pump the liquid through the liquid end, the plunger must be moved. When the plunger is moved out of the liquid cylinder as shown in Figure 2, the pressure of the fluid in the cylinder is reduced. When the pressure becomes less than that in the suction pipe, the suction check valve opens and liquid flows into the cylinder to fill the volume being

FIGURE 1 The volume of liquid displaced by a solid equals the volume of the solid

FIGURE 2 Schematic of the liquid end of reciprocating pump during the suction stroke

vacated by withdrawal of the plunger. During this phase of operation, the discharge check valve is held closed by the higher pressure in the discharged pipe. This portion of the pumping action of a reciprocating positive displacement pump is called the *suction stroke*.

The withdrawal movement must be stopped before the end of the plunger gets to the packing. The plunger movement is then reversed, and the *discharge stroke* portion of the pumping action is started, as illustrated in Figure 3.

Movement of the plunger into the cylinder causes an increase in pressure of the liquid contained therein. This pressure immediately becomes higher than suction pipe pressure and causes the suction valve to close. With further plunger movement, the liquid pressure continues to rise. When the liquid pressure in the cylinder reaches that in the discharge pipe, the discharge check valve is forced open and liquid flows into the discharge pipe. The volume forced into the discharge pipe is equal to the plunger displacement less very small losses. The plunger displacement is the product of its cross-sectional area and the length of stroke. The plunger must be stopped before it hits the bottom of the cylinder. The motion is then reversed, and the plunger again goes on suction stroke as previously described.

The pumping cycle just described is that of a *single-acting* reciprocating pump. It is called single-acting because it makes only one suction stroke and only one discharge stroke in one reciprocating cycle.

Many reciprocating pumps are *double-acting*; that is, they make two suction and two discharge strokes for one complete reciprocating cycle (Figure 4). Most double-acting pumps use as the displacing solid a piston that is sealed to a bore in the liquid cylinder or

FIGURE 3 Schematic of the liquid end of a reciprocating pump during the discharge stroke

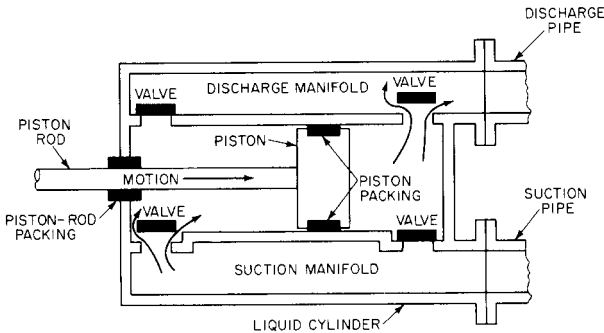

FIGURE 4 Schematic of a double-acting liquid end

to a liquid cylinder liner by pistons with packing. It has two suction and two discharge valves, one of each on each side of the piston. The piston is moved by a piston rod. The piston rod packing prevents liquid from leaking out of the cylinder. When the piston rod and piston are moved in the direction shown, the right side of the piston is on a *discharge stroke* and the left side of the piston is simultaneously on a *suction stroke*. The piston packing must seal tightly to the cylinder liner to prevent leakage of liquid from the high-pressure right side to the low-pressure left side.

The piston must be stopped before it hits the right side of the cylinder. The motion of the piston is then reversed so the left side of the piston begins its discharge stroke and the right side begins its suction stroke.

A reciprocating pump is not complete with a liquid end only; it must also have a driving mechanism to provide motion and force to the plunger or piston. The two most common driving mechanisms are a reciprocating steam engine and a crank-and-throw device. Those pumps using the steam engine are called *direct-acting steam pumps*. Those pumps using the crank-and-throw device are called *power pumps*. Power pumps must be connected to an external rotating driving force, such as an electric motor, steam turbine, or internal combustion engine.

DIRECT-ACTING STEAM PUMPS

Direct-acting steam pumps are mainly classified by the number of working combinations of cylinders. For example, a duplex pump (Figure 5) has two steam and two liquid cylinders mounted side by side, and a simplex pump (Figure 6) has one steam and one liquid cylinder.

Additionally, simplex and duplex pumps may be further defined by (1) cylinder arrangement, whether horizontal or vertical; (2) number of steam expansions in the power end; (3) liquid end arrangement, whether piston or plunger; and (4) valve arrangement, that is, cap and valve plate, side pot, turret type, and so on.

Although this section will refer to steam as the driving medium, compressed gases such as air or natural gas can be used to drive a steam pump. These gases should have oil or mist added to them prior to entering the pump to prevent wear of the steam end parts.

STEAM END CONSTRUCTION AND OPERATION

The driving mechanism, or *steam end*, of a direct-acting steam pump includes the following components, as illustrated in Figure 7:

FIGURE 5 Duplex steam pump

FIGURE 6 Simplex steam pump (Flowservice Corporation)

FIGURE 7 Typical section of duplex steam pump: (1) Steam cylinder with cradle, (2) steam cylinder head, (3) steam cylinder foot, (7) steam piston, (9) steam piston rings, (11) slide valve, (18) steam chest, (19) steam chest cover, (24) valve rod stuffing box gland, (25) piston rod stuffing box, liquid, (26) piston rod stuffing box gland, steam, (33) steam piston rod, (34) steam piston spool, (35) steam piston nut, (38) cross stand, (39) long lever, (41) short lever, (42) upper rock shaft, long crank, (43) lower rock shaft, short crank, (46) crank pin, (49) valve rod link, (54) valve rod, (56) valve rod nut, (57) valve rod head, (58) liquid cylinder, (59) liquid cylinder head, (61) liquid cylinder foot, (62) valve plate, (63) force chamber, (69) liquid piston body, (71) liquid piston follower, (72) liquid cylinder lining, (84) metal valve, (85) valve guard, (86) valve seat, (87) valve spring, (96) drain valve for steam end, (97) drain plug for liquid end, (254) liquid piston rod stuffing box bushing, (332) liquid piston rod, (344) piston rod spool bolt, (374) liquid piston rod nut, (391) lever pin, (431) lever key, (461) crank pin nut, (571) valve rod head pin, (572) valve rod head pin nut, (691) liquid piston snap rings, (692) liquid piston bull rings, (693) liquid piston fibrous packing rings, (997) air cock, (251) liquid piston rod stuffing box, (254A) steam piston rod stuffing box bushing, (261) piston rod stuffing box gland, liquid, (262) piston rod stuffing box gland lining, liquid, (262A) piston rod stuffing box gland lining, steam (Flowserve Corporation)

1. One or more steam cylinders with suitable steam inlet and exhaust connections
2. Steam piston with rings
3. Steam piston rods directly connected to liquid piston rods
4. Steam valves that direct steam into and exhaust steam from the steam cylinder
5. A steam valve actuating mechanism that moves the steam valve in proper sequence to produce reciprocating motion

The operation of a steam pump is quite simple. The motion of the piston is obtained by admitting steam of sufficient pressure to one side of the steam piston while simultaneously exhausting steam from the other side of the piston. There is very little expansion of the steam because it is admitted at a constant rate throughout the stroke. The moving parts, that is, the steam piston, the liquid piston, and the piston rod or rods, are cushioned and brought to rest by exhaust steam trapped in the end of the steam cylinder at the end of each stroke. After a brief pause at the end of the stroke, steam is admitted to the opposite side of the piston and the pump strokes in the opposite direction.

Steam Valves Because the steam valve and its actuating mechanism control the reciprocating motion, any detailed description of the construction of the direct-acting steam pump should rightfully begin with a discussion of steam valve types, operation, and construction.

Duplex Steam Valves The steam valves in a duplex steam pump are less complicated than those in a simplex pump and will be described first. As previously stated, the duplex steam pump can be considered as two simplex pumps arranged side by side and combined to operate as a single unit. The piston rod of one pump, in making its stroke, actuates the steam valve and thereby controls the admission or exhaust of steam in the second pump. A valve gear cross stand assembly is shown in Figure 8. The wishbone-shaped piston rod lever of one side is connected by a shaft to the valve rod crank of the opposite side. The steam valve is connected to the valve rod crank by the steam valve rod and steam valve link. Through this assembly, the piston rod of one side moves the steam valve of the opposite side in the same direction. When the first pump has completed its stroke, it must pause until its own steam valve is actuated by the movement of the second pump before it can make its return stroke. Because one or the other steam cylinder port is always open, there is no “dead center” condition; hence, the pump is always ready to start when steam

FIGURE 8 Steam valve actuating mechanism or a duplex pump (Flowserve Corporation)

FIGURE 9A through C Duplex pump steam valve lost-motion arrangements

is admitted to the steam chest. The movements of both pistons are synchronized to produce a well-regulated flow of liquid free of excessive pulsations and interruptions.

Flat Slide Steam Valves Steam enters the pump from the steam pipe into the steam chest on top of the steam cylinder. Exhaust steam leaves the pump through the center port of five ports, as shown in Figure 9. Most duplex pumps use a flat slide valve that is held against its seat by steam pressure acting upon its entire top area; this is called an *unbalanced valve*. The flat or D valve, as it is often called, is satisfactory for steam pressures up to approximately 250 lb/in² (17 bar¹) and has a reasonable service life, particularly where steam end lubrication is permissible. On large pumps, the force required to move an unbalanced valve is considerable, and so a balanced piston valve, which will be discussed later, is used.

The slide valve shown in Figure 9 is positioned on dead center over the five valve ports. A movement of the valve to the right uncovers the left-side steam port and the right-side exhaust port, which is connected through the slide valve to the center exhaust port. The main steam piston will be moved from left to right by the admitted steam. Movement of the slide valve from dead center to the left would, of course, cause opposite movement of the steam piston.

The steam valves of a duplex pump are mechanically operated, and their movements are dependent upon the motion of the piston rod and the linkage of the valve gear. In order to ensure that one piston will always be in motion when the other piston is reversing at the end of its stroke, lost motion is introduced into the valve gear. Lost motion is a means by which the piston can move during a portion of its stroke without moving the steam valve. Several lost motion arrangements are shown in Figure 9.

¹1 bar = 10⁵ Pa.

If the steam valves are out of adjustment, the pump will have a tendency not to operate through its designed stroke. Increasing the lost motion lengthens the stroke; if this is excessive, the piston will strike the cylinder head. Reducing the lost motion shortens the stroke; if this is excessive, the pump will short-stroke, with a resulting loss in capacity.

The first step in adjusting the valves is to have both steam pistons in a central position in the cylinder. To accomplish this, the piston is moved toward the steam end until the piston strikes the cylinder head. With the piston rod in this position, a mark is made on the rod flush with the steam end stuffing box gland. Next, the piston rod is moved toward the liquid end until the piston strikes, and then another mark is placed on the rod halfway between the first mark and the steam end stuffing box gland. After this, the piston rod is returned toward the steam end until the second mark is flush with the stuffing box gland. The steam piston is now in central position. This procedure is repeated for the opposite piston rod assembly.

The next step is to see that both steam valves are in a central position with equal amounts of lost motion on each side, indicated by distance X in Figure 9.

Most small steam pumps are fitted with a fixed amount of lost motion, as shown in Figure 9a. With the slide valve centered over the valve ports, a properly adjusted pump will have the tappet exactly centered in the space between the valve lugs. The lost motion (X) on each side of the tappet will be equal.

Larger pumps are fitted with adjustable lost motions, such as are shown in Figure 9b. The amount of lost motion (X) can be changed by moving the locknuts. Manufacturers provide specific instructions for setting proper lost motion. However, one rule of thumb is to allow half the width of the steam port on each side for lost motion. A method to provide equality of lost motion is to move the valve each way until it strikes the nut and then note if both port openings are the same.

In some cases, it is desirable to be able to adjust the steam valves while the pump is in motion. With the arrangements previously mentioned, this cannot be done because the steam chest head must be removed. In a pump equipped with a lost-motion mechanism such as that shown in Figure 9c, all adjustments are external and can therefore be made while the pump is in operation.

Balanced Piston Steam Valve The balanced piston steam valve (Figure 10) is used on duplex steam pumps when the slide-type valve cannot be used because of size. The balanced piston valve can also be used without lubrication at pressure above 250 lb/in² (17 bar) and temperatures above 500°F (260°C). At higher pressures, wire drawing or steam cutting can occur as the piston slowly crosses the steam ports. To prevent wear and permanent damage to the steam chest and piston, piston rings are used on the steam valve and a steam chest liner is pressed into the steam chest to protect it.

Cushion Valves Steam cushion valves are usually furnished on larger pumps to act as an added control to prevent the steam piston from striking the cylinder heads when the pump operates at high speeds. As previously shown, the steam end has five ports, the outside ports are for steam admission, and the inside ports are for steam exhaust. As the steam piston approaches the end of the cylinder, it covers the exhaust port, trapping a vol-

FIGURE 10 Balanced piston steam valve: (12) piston valve, (181) steam chest, (23) valve rod stuffing box, (24) valve rod stuffing box gland, (54) valve rod, complete, (57) valve rod head, (14) piston valve ring, (16) piston valve lining, (47) lost-motion block tappet, (491) valve rod link, (563) valve rod collar (Flowserve Corporation)

ume of steam in the end of the cylinder. This steam acts as a cushion and prevents the piston from striking the cylinder head. The cushion valve is simply a bypass valve between the steam and exhaust ports; by opening or closing this valve, the amount of cushion steam can be controlled.

If the pump is running at low speed or working under heavy load, the cushion valve should be opened as much as possible without allowing the piston to strike the cylinder head. If the pump is running at high speed or working under light load, the cushion valve should be closed. The amount of steam cushion and, consequently, the length of stroke can be properly regulated for different operating conditions by the adjustment of this valve.

Simplex Steam Valves The simplex pump steam valve is steam-operated, not mechanically operated as duplex steam valves are. The reason for this is that the piston rod assembly must operate its own steam valve. Consequently the travel of the valve cannot be controlled directly by means of the piston rod motion. Instead, the piston rod operates a pilot valve by means of a linkage similar to that used with a duplex pump. This controls the flow of steam to each end of the main valve, shuttling the steam back and forth. The arrangement illustrated in Figure 11 is one of the designs available to produce this motion.

With the pilot valve in the position shown in Figure 11, steam from the live steam space flows through the pilot valve steam port into the steam space at the left-hand end of the main valve (balanced piston type). Simultaneously, the D section of the pilot valve connects the steam space at the right-hand end of the main valve with the exhaust port, thereby releasing the trapped steam. The main valve has moved completely across to the right end of the chest. The main valve in this position permits steam to flow from the chest to the left steam cylinder port and, at the same time, connects the right steam cylinder port with the exhaust port.

The steam piston now moves to the right, and after the lost motion is taken up in the valve gear, the pilot valve moves to the left. In this position, the cycle previously described now takes place at the opposite end of the steam chest. Because the main valve is steam-operated, it can be in only two positions, either at the left-hand or at the right-hand end of the chest. Hence, it is impossible to have it at dead center. In other words, steam can always flow either to one side or to the other of the steam piston, regardless of the position of the steam piston.

For the valve to operate smoothly and quietly, an arrangement must be provided to create a cushioning effect on the valve travel. The steam piston, as it approaches the end of its travel, cuts off the exhaust port and traps a certain amount of steam, which acts as a cushion and stops the steam piston.

All valve adjustments are outside of the steam chest, and so it is possible to adjust the valve while the pump is in operation. The effect of decreasing or increasing the lost motion is the same as that described for duplex pumps. The lost-motion arrangement is the same as that shown in Figure 9c.

Steam End Materials For most services, cast iron is an excellent material for the steam cylinder and it is the major element of the steam end. It is readily cast in the complicated shape required to provide the steam porting. It possesses good wearing qualities, largely because of its free graphite content. This is required in the piston bores, which are continuously being rubbed by the piston rings. At high steam temperatures and pressures, ductile iron or steel is used. In the latter case, however, cast iron steam cylinder liners are frequently used because of their better wear resistance.

Counterbores are provided at each end of a steam cylinder so the leading piston ring can override, for a part of its width, the end of the cylinder bore to prevent the wearing of a shoulder on the bore.

The cylinder heads and steam pistons are also usually made of cast iron. The cylinder head has a pocket cast in it to receive the piston rod nut at the end of the stroke. Most steam pistons are made in one piece, usually with two piston ring slots machined into the outside circumference.

The relatively wide piston rings are usually made from hammered iron. They are split so they can be expanded to fit over the piston and snapped into the grooves in the piston.

FIGURE 11 Simplex-type steam valve (Flowserve Corporation)

They must be compressed slightly to fit into the bores in the cylinder. This ensures a tight seal with the cylinder bores even as the rings wear during operation. In services where steam cylinder lubrication is not permissible, a combination two-piece ring of iron and bronze is used to obtain longer life than is obtained with the hammered iron rings.

The piston and valve rods are generally made from steel, but stainless steel and Monel are also commonly used. Packing for the rods is usually a braided graphited asbestos.

Drain cocks and valves are always provided to permit drainage of condensation, which forms in the cylinder when a pump is stopped and cools down. On each start-up these must be cracked open until all liquid is drained and only steam comes out; they are then closed.

The steam end and liquid end are joined by a cradle. On most small pumps, the cradle is cast integrally with the steam end. On large pumps, it is a separate casting or fabricated weldment.

LIQUID END CONSTRUCTION

Steam pumps are equipped with many types of liquid ends, each being designed for a particular service condition. However, they can all be classified into two basic types, the piston, or inside-packed, type and the plunger, or outside-packed, type.

The piston pump (Figure 7) is generally used for low and moderate pressures. Because the piston packing is located internally, the operator cannot see the leakage past it or make adjustments that could make the difference between good operation and packing failure. Generally, piston pumps can be used at higher pressures with noncorrosive liquids having good lubricating properties, such as oil, than with corrosive liquids, such as water.

Plunger pumps, illustrated in Figure 12, are usually favored for high-pressure and heavy-duty service. Plunger pumps have stuffing box packing and glands of the same type as those on the piston rods of piston pumps. All packing leakage is external, where it is a guide to adjustments that control the leakage and extend packing and plunger life. During operation, lubrication can be supplied to the external plunger packing to extend its life. Lubrication cannot be supplied to the piston packing rings on a piston pump.

Piston-Type Liquid Ends The most generally used piston pump is the cap-and-valve plate design, illustrated in Figure 7. This is usually built for low pressures and temperatures, although some designs are used at up to 350 lb/in² (246 bar) of discharge pressure and 350°F (177°C). The discharge valve units are mounted on a plate separate from the cylinder and have a port leading to the discharge connection. A dome-shaped cap, subject to discharge pressure, covers the discharge valve plate. The suction valve units are mounted in the cylinder directly below their respective discharge valves. A passage in the liquid cylinder leads from below the suction valves down between the cylinders of a duplex pump to the suction connection.

FIGURE 12 Simplex-type plunger pump (Flowserve Corporation)

FIGURE 13A and B Side-pot piston pump (Flowserve Corporation)

Side-pot liquid ends are used where the operating pressures are beyond the limitations of the cap-and-valve-plate pump. Figure 13 illustrates this design. Suction valves are placed in individual pots on the side of the cylinders and discharge valves in the pots above the cylinders. Each valve can be serviced individually by removing its cover. The small area of the valve covers exposed to discharge pressure makes the sealing much simpler than is the case in the cap-and-valve design. Side-pot liquid ends are widely used in refinery and oil field applications. This design is commonly employed to the maximum pressure practicable for a piston pump.

There are several specially designed piston-type liquid ends that have been developed for specific applications. One of these is the close-clearance design illustrated in Figures 14 and 15. This pump can handle volatile liquids, such as propane or butane, or a liquid that may contain entrained vapors.

The close-clearance cylinder is designed to minimize the dead space when the piston is at each end of its stroke. The liquid valves are placed as close as possible to the pump chamber to keep clearance to a minimum. The suction valves are positioned below the cylinder at the highest points in the suction manifold to ensure that all the gases are passed into the pump chamber. Although these pumps are of close-clearance design, they are not compressors and can vapor-bind; that is, a large amount of gas trapped below the discharge valve will compress and absorb the entire displacement of the pump. When this occurs, the dis-

FIGURE 14 Close-clearance liquid end pump (Flowserve Corporation)

FIGURE 15 End views of close-clearance liquid end pump, showing disk valve assembly and wing valve assembly (Flowserve Corporation)

charge valve will not open and this will cause a loss of flow. Hand-operated bypass or priming valves are provided to bypass the discharge valve and permit the trapped gases to escape to the discharge manifold. When the pump is free of vapors, the valves are closed.

FIGURE 16 A pump for handling viscous liquid (Flowserve Corporation)

TABLE 1 Material and service specifications for pump liquid ends

| Part | Regular fitted (RF) | Bronze fitted (BF) | Fully bronze fitted (FBF) | All iron fitted (AIF) | All bronze (AB) |
|------------------------------------|---|--|--|---|---|
| Cylinders | Cast iron | Cast iron | Cast iron | Cast iron | Bronze |
| Cylinder liners | Bronze | Bronze | Bronze | Cast iron | Bronze |
| Piston | Cast iron | Cast iron | Bronze | Cast iron | Bronze |
| Piston packing | Fibrous | Fibrous | Fibrous | Cast-iron, 3-ring | Fibrous |
| Stuffing box | Cast iron, bronze bushed | Cast iron, bronze bushed | Cast iron, bronze bushed | Cast iron | Bronze |
| Piston rod | Steel | Bronze | Bronze | Steel | Bronze |
| Valve service | Bronze | Bronze | Bronze | Steel | Bronze |
| Services for which most often used | Cold water; other cold liquids not corrosive to iron and bronze | Same as for RF, with reduced maintenance; continuous hot water | Boiler feed; intermittent hot-water; sodium chloride, brines | Oils and other hydrocarbons not corrosive to iron or steel; caustic solutions | Mild acids that would attack iron cylinders but not acid-resisting bronze |

There are a number of other special piston pump designs for certain services in addition to the most common types just described. One of these special designs is the wet vacuum pump, which features tight-sealing rubber valves that permit the pump to handle liquid and air or non-condensable vapors. Another special design is made of hard, wear-resistant materials to pump cement grout on construction projects. Another design, shown in Figure 16, has no suction valves and is made for handling viscous products such as sugarcane pulp, soap, white lead, printer's ink, and tar. The liquid flows into the cylinder from above through a suction port that is cut off as the piston moves back and forth.

Piston Pump Liquid End Materials and Construction The materials used for piston pump liquid ends vary widely with the liquids handled. Most of the services to which these pumps are applied use one of the common material combinations listed in Table 1.

The liquid cylinder, the largest liquid end component, is most frequently made from cast iron or bronze. However, other materials are also used. Cast steel cylinders are used in refineries and chemical plants for high-pressure and high-temperature applications. Nickel cast steels are used for low-temperature services. Ni-Resist cast iron, chrome-alloy steels, and stainless steels are occasionally used for certain corrosive and abrasive applications, but tend to make pump cost very high. The liquid cylinder heads and valve covers are usually made from the same material as the liquid cylinder.

As was the case in the steam end, a liquid cylinder liner is used to prevent wear and permanent damage to the liquid cylinder. Liners must be replaced periodically when worn by the piston packing to the point that too much fluid leaks from one side of the piston to the other. The liners may be either of a driven-in (or pressed-in) type or of a removable type, which is bolted or clamped in position in the cylinder bore.

The pressed-in type (Figure 7) derives its entire support from the drive fit in the cylinder bore. As a rule, such a liner is relatively thin and is commonly made from a centrifugal casting or a cold-drawn brass tube. After a driven liner is worn to the point where it must be replaced, it is usually removed by chipping a narrow groove along its entire length. This groove is cut as closely as possible through the liner without damaging the wall of the cylinder bore. A flange on the liner fits into a recess at the beginning of the cylinder bore. This flange is held in contact with a shoulder by jack bolts or a spacer between the cylinder head and the end of the liner. Sometimes a packing ring is used between the flange and shoulder for a positive seal. Removable liners are heavier than pressed-in ones.

There are several designs of pistons and piston packings used for various applications. The three most common are as follows:

1. The body-and-follower type of piston with soft fibrous packing or hard-formed composition rings (Figure 17). The packing is installed in the packing space on the piston with a clearance in both length and depth. This clearance permits fluid pressure to act on one end and the inside of the packing to hold and seal it against the other end of the packing space and the cylinder liner bore.
2. The solid piston or, as shown in Figure 18, a body and follower with rings of cast iron or other materials. This type is commonly used in pumps handling oil or other hydrocarbons. The metal rings are split with an angle or step-cut joint. Their natural tension keeps them in contact with the cylinder liner, assisted by fluid pressure under the ring.
3. The cup piston (Figure 19), which consists of a body-and-follower type of piston with molded cups of materials such as rubber reinforced with fabric. Fluid pressure on the inside of the cup presses the lip out against the cylinder bore, forming a tight seal.

The piston rod stuffing boxes are usually made separate from, but of the same material as, the liquid cylinder. When handling liquids with good lubrication properties, the stuffing boxes are usually packed full with a soft, square, braided packing that is compatible with the liquid. When the liquid has poor lubricating properties, a lantern ring is

FIGURE 17 Body-and-follower piston

FIGURE 18 Body-and-follower piston with snap rings

FIGURE 19 Body-and-follower piston with molded cups

FIGURE 20 Stem-guided disk valve

FIGURE 21 Wing-guided valve

FIGURE 22 Semispherical valve

installed in the center of the stuffing box with packing rings on both sides of it. A drilled hole is provided through which a lubricant, grease or oil, can be injected into the lantern ring from the outside of the stuffing box. At higher temperatures, approximately 500°F (260°C) or higher, a cooling water jacket is added to the outside of the stuffing box or as a spacer between the stuffing box and the liquid cylinder. The purpose of the cooling water jacket is to extend packing life by keeping the packing cool.

The liquid end valves of all direct-acting steam pumps are self-acting, in contrast to the mechanically operated slide valves in the steam end. The liquid end valves act like check valves; they are opened by the liquid passing through and are closed by a spring plus their weight.

Liquid end valves are roughly divided into three types: the disk valve for general service and thin liquids, the wing-guided valves for high pressures, and either the ball or the semispherical valve for abrasive and viscous liquids.

The valve shown in Figure 20 is typical of the disk type. This stem-guided design is commonly used in the cap-and-valve plate design. For hot-water boiler-feed and general service, the disk, seat, and stem are usually made of bronze, although other alloys may also be used. For lower temperatures and pressures, the disk may be made of rubber, which has the advantage of always forming a tight seal with the valve seat.

The wing-guided valve shown in Figure 21 is typical of the design use for high pressures. It derives its name from the wings on the bottom of the valve, which guide it in its seat. The beveled seating surfaces on the valve and seat tend to form a tighter seal than the flat seating surfaces on a disk valve. There is also less danger that a solid foreign particle in the liquid will be trapped between the seat and the valve. This type of valve is commonly made from a heat-treated chrome-alloy-steel forging, although a cast hard bronze and other materials may be used.

The ball valve, as its name suggests, is a ball that acts like a check valve. It is usually not spring-loaded, but guides and lift stops are provided as necessary to control its operation. The ball may be made of rubber, bronze, stainless steel, or other materials as service conditions require. The semispherical valve (Figure 22) is spring-loaded and can therefore be operated at higher speeds than the ball valve. Both the ball and the semispherical type

have the advantage of having no obstructions to flow in the valve seat (the disk valve seat has ribs and the wing-guided valve has vanes which obstruct the flow). The one large opening in the seat and the smooth spherical surface of ball and semispherical valves minimize the resistance to flow of viscous liquids. These types are also used for liquids with suspended solids because their rolling seating action prevents trapping of the solids between the seat and valve.

Plunger-Type Liquid Ends As mentioned previously, plunger-type pumps are used where dependability is of prime importance, even when the pump is operated continuously for long periods and where the pressure is very high. Cast liquid end plunger pumps are used for low and moderate pressures. Forged liquid end pumps (Figure 23), which are the most common plunger types, are used for high pressures and have been built to handle pressures in excess of 10,000 lb/in² (69 MPa).

Most of these designs have opposed plungers; that is, one plunger operating into the inboard end of the liquid cylinder and one into the outboard end. The plungers are solidly secured to inboard and outboard plunger crossheads. The inboard and outboard plunger crossheads are joined by side rods positioned on each side of the cylinder. With this arrangement, each plunger is single-acting; that is, it makes only one pressure stroke for each complete reciprocating cycle. The pump, however, is double-acting because the plungers are connected by the side rods.

PLUNGER PUMP LIQUID END MATERIALS The liquid cylinder of a forged liquid end plunger-type pump is most commonly made from forged steel, although bronze, Monel, chrome alloy, and stainless steels are also used. The stuffing boxes and valve chambers are usually integral with the cylinder (Figure 23), which is desirable for higher temperatures and pressures because high-temperature joints are minimized.

The liquid plungers may be made of a number of materials. The plungers must be as hard and smooth as possible to reduce friction and to resist wear by the plunger packing. Hardened chrome-alloy steels and steel coated with hard-metal alloys or ceramics are most commonly used.

The stuffing box packing used will vary widely depending upon service conditions. A soft, square packing cut to size may be used. However, solid molded rings of square, V-lip, or U-lip design are commonly used at higher pressures. Oil or grease is frequently injected into a lantern ring in the center of the stuffing box to reduce friction and reduce packing and plunger wear.

The liquid valves may be of any of the types or materials described above. However, the wing-guided valve with beveled seating surfaces is the most common because it is most suitable for high pressures.

DIRECT-ACTING STEAM PUMP PERFORMANCE

The direct-acting steam pump is a very flexible machine. It can operate at any point of pressure and flow within the limitations of the particular design. The speed of, and therefore the flow from, the pump can be controlled from stop to maximum by throttling the steam supply. This can be done by either a manual or an automatically operated valve in the steam supply line. The maximum speed of a particular design is primarily limited by the frequency with which the liquid valves will open and close smoothly. The pump will operate against any pressure imposed upon it by the system it is serving, from zero to its maximum pressure rating. The maximum pressure rating of a particular design is determined by the strength of the liquid end. In a particular application, the maximum liquid pressure developed may be limited by the available steam pressure and by the ratio of the steam piston and liquid piston areas.

STEAM PUMP CAPACITY

The flow to the discharge system is termed the pump *capacity*. The capacity, usually expressed in U.S. gallons per minute (cubic meters per minute), is somewhat less than the

FIGURE 23 Simplex plunger pump with forged steel cylinder: (1) steam cylinder with cradle, (2) steam cylinder head, (3) steam cylinder foot, (7) steam piston, (9) steam piston rings, (11) slide valve, (12) piston valve, (18) steam chest, (19) steam chest cover, (22) steam chest head, (24) valve rod stuffing box gland, (26) steam piston rod stuffing box gland, (33) steam piston rod, (35) steam piston rod nut, (36) plunger nut, (38) cross stand, (39) lever, (42) fulcrum pin, (44) crank, (47) tappet, (49) valve rod link, (49A) valve rod link head, (52) lost-motion adjusting nut, (53) lost-motion locknut, (54) valve rod, (57) valve rod head, (61) liquid cylinder foot, (73) plunger, (75) plunger lining, (76) plunger gland flange, (77) plunger gland lining, (78) side rod, (78A) side rod guide, (82) plunger crosshead, front; (84) metal valve, (86) valve seat, (87) valve spring, (96) steam cylinder drain valve, (254) piston rod stuffing box bushing, (431) lever key, (432) crank key, (571) valve rod head pin, (585) liquid cylinder, (781) side rod nut, (821) plunger crosshead, rear, (891) suction valve plug, (945) crosshead pin, (2612) lantern gland, (8911) discharge valve plug, (3411) steam piston rod jam nut (Flowserve Corporation)

theoretical *displacement* of the pump. The difference between displacement and capacity is called *slip*. The displacement is a function of the area of the liquid piston and the speed at which the piston is moving.

The displacement of a single double-acting piston can be calculated from the formula

$$\text{in USCS units} \quad D = \frac{12 \times AS}{231} \text{ or } 0.0408 d^2 S$$

$$\text{in SI units} \quad D = 1 \times 10^{-6} \times AS$$

where D = displacement, gpm (m^3/min)

A = area of piston or plunger, in^2 (mm^2)

S = piston speed, ft/min (m/min)

d = diameter of the liquid piston or plunger, in (mm)

For a duplex double-acting pump, D is multiplied by 2. This formula neglects the area of the piston rod. For very accurate calculations, it is necessary to deduct the rod area from the piston area. This is normally not done, and the resultant loss is usually considered part of the slip.

The slip also includes losses due to leakage from the stuffing boxes, leakage across the piston on packed-piston pumps, and leakage back into the cylinder from the discharge side while the discharge valves are closing. Slip for a given pump is determined by a test. For a properly packed pump, slip is usually 3 to 5%. As a pump wears, slip will increase, but this can be compensated for by increasing the pump speed to maintain the desired capacity.

PISTON SPEED

Although piston speed in feet per minute (meters per minute) is the accepted term used to express steam pump speed, it cannot easily be measured directly and is usually calculated by measuring the revolutions per minute of the pump and converting this to piston speed. One revolution of a steam pump is defined as one complete forward and reverse stroke of the piston. The relationship between piston speed and rpm is

$$\text{in USCS units} \quad S = \frac{\text{rpm} \times \text{stroke}}{6}$$

$$\text{in SI units} \quad S = 0.002 \times \text{rpm} \times \text{stroke}$$

where S = piston speed, ft/min (m/min)

rpm = revolutions per minute

stroke = stroke of pump, in (mm)

A steam pump must fill with liquid from the suction supply on each stroke, or it will not perform properly. If the pump runs too fast, the liquid cannot flow through the suction line, pump passageways, and valves fast enough to follow the piston. On the basis of experience and hydraulic formulas, maximum piston speeds that vary with the length of stroke and the liquid handled can be established.

Table 2 shows general averages of maximum speed ratings for pumps of specified stroke handling various liquids. Some pumps, by reason of exceptionally large valve areas or other design features, may be perfectly suitable for speeds higher than shown. From the table, it should be noted that piston speed should be reduced for viscous liquids. Unless the net positive suction head is proportionately high, viscous liquids will not follow the piston at high speeds because frictional resistance in suction lines and in the pump increases with viscosity and rate of flow. Pumps handling hot water are run more slowly to prevent boiling of the liquid as it flows into the low-pressure area behind the piston.

TABLE 2 Average maximum speed ratings

*SI conversion factors: in \times 25.4 = mm; ft/min \times 0.3048 = m/min.

SIZE OF LIQUID END

The size of a steam pump is always designated as follows:

Steam piston diameter \times liquid piston diameter \times stroke

For example, a $\frac{1}{2} \times 5 \times 6$ steam pump has a $7\frac{1}{2}$ -in (191-mm) diameter steam piston, a 5-in (127-mm) diameter liquid piston, and a 6-in (152-mm) stroke.

To determine the liquid piston diameter for a specified capacity, the following procedure is used. First, a reasonable stroke length is assumed and the maximum piston speed for this stroke and the type of liquid pumped is selected from Table 2. Then the desired capacity is increased by 3 to 5% to account for slip. The result is the desired displacement. Then for either a simplex or duplex pump, the liquid piston diameter can be calculated as follows:

In USCS units, for simplex pumps: $d_l = 4.95 \left(\frac{D}{S} \right)^{1/2}$

For duplex pumps: $d_l = 3.5 \left(\frac{D}{S} \right)^{1/2}$

In SI units, for simplex pumps: $d_l = 1128.4 \left(\frac{D}{S} \right)^{1/2}$

For duplex pumps: $d_l = 797.9 \left(\frac{D}{S} \right)^{1/2}$

where d_l = liquid piston diameter, in (mm)

D = displacement, gpm (m^3/min)

S = piston speed, ft/min (m/min)

Using the resultant liquid piston diameter, the next larger standard piston size is selected.

SIZE OF STEAM END

To calculate the size of the steam end required for a specific application, the basic principle of steam pump operation should be considered. A simple schematic of a steam pump is shown in Figure 24.

In order for the pump to move, the force exerted on the steam piston must exceed the force on the liquid piston that is opposing it. The force on the steam piston is the product of the net steam pressure and the steam piston area. The *net* steam pressure is the steam inlet pressure minus the exhaust pressure. The force acting on the liquid piston is the product of the net liquid pressure and the liquid piston area. The *net* liquid pressure is the pump discharge pressure minus the suction pressure or *plus* the suction lift. This may be expressed algebraically as follows:

$$P_s A_s > P_l A_l$$

where P_s = net steam pressure, lb/in² (bar)

A_s = steam piston area, in² (mm²)

P_l = net liquid pressure, lb/in² (bar)

A_l = liquid piston area, in² (mm²)

Because the pistons are circular, the squares of their diameters are directly proportional to their areas, and the above formula can be rewritten as

$$P_s d_s^2 > P_l d_l^2$$

where d_s = steam piston diameter, in (mm)

d_l = liquid piston diameter, in (mm)

In practice, it is necessary for the force on the steam piston to exceed the force opposing it on the liquid piston by a considerable amount. This is because of mechanical losses, which include stuffing box friction, friction between piston rings and cylinder of both liquid and steam ends, and the operation of the valve gear. These losses are determined by testing and are accounted for in size calculations by introduction of a mechanical efficiency figure. Mechanical efficiencies are expressed as a percentage, with 100% being a perfect balance of forces acting on the steam and liquid pistons as expressed in the previous formula. Because the efficiencies of two identical pumps may vary with stuffing box and piston ring packing tightness, the efficiencies published by manufacturers tend to be conservative.

With the mechanical efficiency factor inserted, the formula of forces becomes

$$P_s d_s^2 E_m = P_l d_l^2$$

where P_s = net steam pressure, lb/in² (bar)

d_s = steam piston diameter, in (mm)

FIGURE 24 Schematic showing direction of forces on pistons

TABLE 3 Typical mechanical efficiency values

| Stroke length, in (mm) | Mechanical efficiency, % | |
|------------------------|--------------------------|--------------|
| | Piston Pump | Plunger pump |
| 3 (76) | 50 | 47 |
| 4 (102) | 55 | 52 |
| 5 (127) | 60 | 57 |
| 6 (152) | 65 | 61 |
| 8 (201) | 65 | 61 |
| 10 (254) | 70 | 66 |
| 12 (305) | 70 | 66 |
| 18 (457) | 73 | 69 |
| 24 (610) | 75 | 71 |

P_l = net liquid pressure, lb/in² (bar)

d_l = liquid piston diameter, in (mm)

E_m = mechanical efficiency, expressed as a decimal

This formula is commonly used to determine the *minimum* size of steam piston required when the liquid piston size has already been selected and the net steam and net liquid pressures are known. For this calculation, the formula is rearranged to the form

$$d_s = d_l \left(\frac{P_l}{P_s E_m} \right)^{1/2}$$

The efficiency of a long-stroke pump is greater than that of a short-stroke pump. Although mechanical efficiency varies with stroke length, any two pumps of the same size are capable of the same efficiency.

Table 3 shows typical mechanical efficiencies that can be used to determine required steam end size.

STEAM CONSUMPTION AND WATER HORSEPOWER

After determining the proper size of other pump types, the next concern usually is to calculate the maximum brake horsepower so the proper size of driver can be selected. With a steam pump, the next step is usually to determine the steam consumption. This must be known to ensure that the boiler generating the steam is large enough to supply the steam required by the pump as well as that required for all its other services.

To determine the steam consumption, it is necessary first to calculate the water horsepower as follows:

In USCS units
$$whp = \frac{Q \times P_l}{1715}$$

In SI units
$$kW = \frac{Q \times P_l}{36}$$

where whp = water horsepower

Q = pump capacity, gpm (m³/h)

P_l = net liquid pressure, lb/in² (bar)

FIGURE 25 Approximate steam consumption for steam pumps (pounds of steam per water horsepower-hour = 1.644 kg of steam per water kilowatt-hour; water horsepower per cylinder = 1.341 kW per cylinder; ft/s = 0.3047 m/s; in = 25.44 mm) (Hydraulic Institute Standards, 12th Edition, 1969—out of print)

A steam consumption chart (Figure 25) affords a means of quickly obtaining an approximate figure for the steam rate of direct-acting steam pumps. For duplex pumps, divide the water horsepower by 2 before applying it to the curves. These curves were made up on the basis of water horsepower per cylinder; if the above procedure is not followed, the results will be inaccurate.

Starting with the water horsepower per cylinder:

1. Move vertically to the curve for steam cylinder size.
2. Move horizontally to the curve for 50-ft/min (15.15-m/min) piston speed. This is the basic curve from which the other curves were plotted.
3. Move vertically to the piston speed at which the pump will run.
4. Move horizontally to the steam rate scale and read it in pounds per water horsepower-hour (kilograms per kilowatt-hour).
5. Multiply the result by total water horsepower to obtain the steam rate in pounds per hour (kilograms per hour).

For steam cylinders with diameters as shown, but with longer stroke, deduct 1% from the steam rate for each 20% of additional stroke. Thus, a 12×24 steam end will have a steam consumption about 5% less than a 12×12 steam end. For $5\frac{1}{4} \times 5$ and $4\frac{1}{2} \times 4$ steam ends, the 6×6 curve will give approximate figures. For cylinders of intermediate diameters, interpolate between the curves.

To correct for superheated steam, deduct 1% for each 10° of superheat. To correct for back pressure, multiply the steam rate by a correction factor equal to

$$\left(\frac{P + BP}{P} \right)^{1/2}$$

where P = net steam pressure to drive pump, lb/in² (bar)

BP = back pressure, lb/in² (bar)

Direct-acting steam pumps have inherently high steam consumption. This is not necessarily a disadvantage, however, when the exhaust steam can be used for heating the boiler-feed water or for building heating or process work. Because these pumps can operate with a considerable range of back pressure, it is possible to recover nearly all the heat in the steam required to operate them. Because they do not use steam expansively, they are actually metering devices rather than heat engines and as such consume heat from the steam only as the heat is lost via radiation from the steam end of the pump. These pumps act, in effect, like a reducing valve to deliver lower pressure steam that contains nearly all its initial heat.

SUCTION SYSTEMS AND NET POSITIVE SUCTION HEAD

A majority of pump engineers agree that most operating problems with pumps of all types are caused by failure to supply adequate suction pressure to fill the pump properly.

The steam pump industry uses the term *net positive suction head required* (*NPSHR*) to define the head, or pressure, required by the pump over its datum, usually the discharge valve level. This pressure is needed to (1) overcome frictional losses in the pump, (2) overcome the weight and spring loadings of the suction valves, and (3) create the desired velocity in the suction opening and through the suction valves. The *NPSHR* of a steam pump will increase as the piston speed and capacity are increased. The average steam pump will have valves designed to limit the *NPSHR* to 5 lb/in² (0.3 bar) (34.5 MPa) or less at maximum piston speed.

If the absolute pressure in the suction system minus the vapor pressure is inadequate to meet or exceed the *NPSHR*, the pump will cavitate. Cavitation is the change of a portion of the liquid to vapor, and it causes a reduction in delivered capacity, erratic discharge pressure, and noisy operation. Even minor cavitation will require frequent refacing of the valves, and severe cavitation can cause cracked cylinders or pistons or failure of other major parts.

FLOW CHARACTERISTICS

The flow characteristics of duplex and simplex pumps are illustrated in Figure 26. The flow from a simplex pump is fairly constant except when the pump is at rest. However,

FIGURE 26 Flow characteristics of simplex and duplex pumps

because the flow must stop for the valves to close and for the forces on both sides of the steam and liquid pistons to reverse, there is uneven and pulsating flow. This can be compensated for, in part, by installing a pulsation-dampening device on the discharge side of the pump or in the discharge line.

In a duplex pump, one piston starts up just before the other piston completes its stroke, and the overlapping of the two strokes eliminates the sharp capacity drop.

SECTION 3.4

DISPLACEMENT PUMP PERFORMANCE, INSTRUMENTATION, AND DIAGNOSTICS

J. C. WACHEL
FRED R. SZENASI

The most common operational and reliability problems in reciprocating positive displacement pump systems are characterized by

- Low net positive suction head (*NPSH*), pulsations, pressure surge, cavitation, waterhammer
- Vibrations of pump or piping
- Mechanical failures, wear, erosion, alignment
- High horsepower requirements, high motor current, torsional oscillations
- Temperature extremes, thermal cycling
- Harsh liquids: corrosive, caustic, colloidal suspensions, precipitates (slurries)

Although any component in a pump system may be defective, most operational problems are caused by liquid transient interaction of the piping system and pump system or by purely mechanical interaction of the pump, drive system, foundation, and so on. This section discusses hydraulic and mechanical problems and suggests measurement and diagnostic procedures for determining the sources of these problems.

HYDRAULIC AND MECHANICAL PUMP PROBLEMS

Inadequate *NPSH* Net positive suction head available (*NPSHA*) is the static head plus atmospheric head minus lift loss, frictional loss, vapor pressure, and acceleration head available at the suction connection centerline.

Acceleration head can be the highest factor of *NPSHA*. In some cases, it is 10 times the total of all the other losses. Data from both the pump and the suction system are required

FIGURE 1 Organ pipe resonant mode shapes

to determine acceleration head; its value cannot be calculated until these data have been established. Inadequate *NPSH* can cause cavitation, the rapid collapse of vapor bubbles, which can result in a variety of pump problems, including noise, vibration, loss of head and capacity, and severe erosion of the valves and surfaces in the adjacent inlet areas. To avoid cavitation of liquid in the pump or piping, the absolute liquid static pressure at pumping temperatures must always exceed the vapor pressure of the liquid. The pressure at the pump suction should include sufficient margin to allow for the presence of pulsations as well as pressure losses due to flow.

Positive Displacement Pump Pulsations The intermittent flow of a liquid through pump internal valves generates liquid pulsations at integral multiples of the pump operating speed. For example, a 120-rpm triplex pump generates pulsations at all multiples of pump speed (2 Hz, 4 Hz, and so on); however, the most significant components will usually be multiples of the number of plungers (6 Hz, 12 Hz, 18 Hz, and so on). Resultant pulsation pressures in the piping system are determined by the interaction of the generated pulsation spectrum from the pump and the acoustic length resonances of liquid in the piping. For variable-speed units, the discrete frequency components change in frequency as a function of operating speed and the measured amplitude of any pulsation harmonic can vary substantially with changes in the location of the measurement point relative to the pressure nodes and antinodes of the standing wave pattern.

Piping System Pulsation Response Because acoustic liquid resonances occur in piping systems of finite length, these resonances will selectively amplify some pulsation frequencies and attenuate others. Resonances of individual piping segments can be described from organ pipe acoustic theory. The resonant frequencies of standing pressure waves depend upon the velocity of sound in the liquid being pumped, pipe length, and end conditions. The equations for calculating these frequencies are shown in Figure 1. All of the integral multiples (N) of a resonance can occur, and it is desirable to mismatch the excitation frequencies from any acoustical resonances. A 2:1 diameter increase or greater would represent an open end for the smaller pipe. Closed valves, pumps, or a 2:1 diameter reduction represent closed ends. For example, a 2-in (51-mm) diameter pipe that connects radially into two 8-in (203-mm) diameter volumes would respond acoustically as an open-end pipe.

Complex piping system responses depend upon the termination impedances and interaction of acoustical resonances and cannot be handled with simplified equations. An electroacoustic analog¹ or digital computer can be used for the more complex systems.

Velocity of Sound in Liquid Piping Systems The acoustic velocity of liquids can be determined by the following equation:

$$a = C_1 \sqrt{\frac{K_s}{\text{sp. gr.}}} \quad (1)$$

where a = velocity of sound, ft/s (m/s)

C_1 = 8.615 for USCS units, 1.0 for SI units

K_s = isentropic bulk modulus, lb/in² (kPa)

sp. gr. = specific gravity

In liquid piping systems, the acoustic velocity can be significantly affected by pipe wall flexibility. The acoustic velocity can be adjusted by the following equation:

$$a_{\text{adjusted}} = a \sqrt{\frac{1}{1 + \frac{DK_s}{tE}}} \quad (2)$$

where D = pipe diameter, in (mm)

t = pipe wall thickness, in (mm)

E = elastic modulus of pipe material, lb/in² (kPa)

Pipe wall radial compliance can reduce the velocity of sound in liquid in a pipe as shown in Figure 2.²

The bulk modulus of water can be calculated with the following equation³ for temperatures from 0 to 212°F (0 to 100°C) and pressures from 0 to 4.4×10^4 lb/in² (0 to 3 kbar*):

$$K_s = K_0 + 3.4P \quad (3)$$

where K_s = isentropic bulk modulus, kbar

K_0 = constant from Table 1, kbar

P = pressure, kbar

(1 kbar = 10^5 kPa = 14,700 lb/in²)

FIGURE 2 Velocity of sound in water at 14.6 lb/in² (1 bar), 60°F (15.6°C) versus nominal pipe size with 0.25-in (6.35-mm) wall thickness

*1 bar = 10^5 Pa.

TABLE 1 Constant K_0 for evaluation of isentropic bulk modulus of water from 0 to 3 kbar

| Temperature, °C (°F) | | Isentropic constant K_0 , kbar ^a |
|----------------------|-------|---|
| 0 | (32) | 19.7 |
| 10 | (50) | 21.0 |
| 20 | (68) | 22.0 |
| 30 | (86) | 22.7 |
| 40 | (104) | 23.2 |
| 50 | (122) | 23.5 |
| 60 | (140) | 23.7 |

FIGURE 3 Isothermal secant bulk modulus at 20,000 lb/in² gage for petroleum oils
(1 lb/in² = 6.895 kPa; °C = (°F - 32)/1.8).

The calculation of the isentropic bulk modulus of water is accurate to $\pm 0.5\%$ at 68°F (20°C) and lower pressures.⁴ At elevated pressures (greater than 3 kbar) and temperatures (greater than 100°C), the error should not exceed $\pm 3\%$.

The bulk modulus for petroleum oils (hydraulic fluids) can be obtained at various temperatures and pressures by using Figures 3 and 4, which were developed by the American

FIGURE 4 Pressure correction for isothermal secant bulk modulus for petroleum oils ($1 \text{ lb/in}^2 = 6.895 \text{ kPa}$)

Petroleum Institute (API).⁴⁻⁷ Figure 3 relates density (mass per unit volume) and temperature to the isothermal secant bulk modulus at $20,000 \text{ lb/in}^2$ ($137,900 \text{ kPa}$), and Figure 4 corrects for various pressures.

The isentropic tangent bulk modulus is needed to calculate the speed of sound in hydraulic fluids and can be readily obtained from Figures 3 and 4 as follows:

1. Read the isothermal secant bulk modulus at the desired temperature from Figure 3.
2. Using the value for isothermal secant bulk modulus obtained from Figure 3, go to Figure 4 and locate the intersection of the pressure line with that value. Move vertically to the pressure line representing twice the normal pressure. Read the adjusted isothermal secant bulk modulus for the double value of pressure.
3. Multiply the adjusted isothermal secant bulk modulus by 1.15 to obtain the value of the isentropic tangent bulk modulus (compensation for the ratio of specific heats).

The isothermal tangent bulk modulus has been shown to be approximately equal to the secant bulk modulus at twice the pressure⁵ within $\pm 1\%$. The relationship between isothermal bulk modulus K_t and isentropic bulk modulus K_s is

$$K_s = K_t c_p / c_v \quad (4)$$

The value of c_p / c_v for most hydraulic fluids is approximately 1.15.

Pulsation Control Pulsation control can be achieved by judicious use of acoustic filters and side branch accumulators. Acoustic filters are liquid-filled devices consisting of volumes and chokes that use reactive filtering techniques to attenuate pulsations. Side

$$\mu_j = \frac{A_j}{L_j + 1/2 \sqrt{\pi A_j}} \quad \text{for } j = 1, 2, 3$$

$$f = \frac{a}{2\pi} \sqrt{\frac{1}{2} \left[\frac{\mu_1 + \mu_2}{v_1} + \frac{\mu_2 + \mu_3}{v_2} \pm \sqrt{\left(\frac{\mu_1 + \mu_2}{v_1} - \frac{\mu_2 + \mu_3}{v_2} \right)^2 + \frac{4\mu_2^2}{v_1 v_2}} \right]}$$

FOR EQUAL VOLUMES, THE RESONANT FREQUENCY IS APPROXIMATELY:

$$f = \frac{a}{\sqrt{2} \pi} \sqrt{\frac{\mu_2}{v_1}}$$

FIGURE 5 Two-chamber resonator system with both ends open. V = volume, ft^3 (m^3); f = resonant frequency, Hz; L = choke tube length, ft (m); A = choke tube area, ft^2 (m^2); a = acoustic velocity, ft/s (m/s); m = acoustic parameter.

branch resonators are of two types: quarter-wavelength resonant stubs and gas-charged accumulators. (The terms *accumulators*, *dampeners*, and *dampers* are used interchangeably in the liquid filter industry.)

Acoustic Filters An acoustic filter consisting of two volumes connected by a small-diameter choke can significantly reduce the transmission of pulsations from the pump into the suction and discharge piping systems. The equations given in Figure 5 can be used to calculate the resonant frequency for a simple volume-choke-volume filter. The filter should be designed to have a resonant frequency no more than one-half the lowest frequency desired to be reduced, referred to as the cutoff frequency. Such a filter is called a low-pass filter because it attenuates frequencies above the cutoff frequency.

A special case for symmetric liquid-filled filters can be obtained by choosing equal chamber and choke lengths. This reduces the equation in Figure 5 to

$$f = \frac{ad}{\pi \sqrt{2} CD} \quad (5)$$

where d = choke diameter, in (mm)

L = chamber and choke length, ft (m)

D = chamber diameter, in (mm)

Normally, a good filter design will have a resonant frequency less than one-half the plunger frequency and will have a minimal pressure drop. For example, a triplex pump running at 600 rpm generates pulsations at all multiples of 10 Hz. The largest amplitudes

would normally be at 30 Hz, 60 Hz, 90 Hz, and so on. The filter resonant frequency should be set at 15 Hz or lower. For water, in which the velocity of sound is 3200 ft/s (976 m/s), and a volume bottle size inner diameter of 19 in (482.6 mm),

$$\text{in USCS units} \quad \frac{L}{d} = \frac{3200}{\pi \sqrt{2} (15)(19)} = 2.53 \frac{\text{ft}}{\text{in}}$$

$$\text{in SI units} \quad \frac{L}{d} = \frac{976}{\pi \sqrt{2} (15)(482.6)} = 0.03 \frac{\text{m}}{\text{mm}} \quad (6)$$

If the choke diameter is selected to be 1.049 in (26.64 mm), the length of each volume bottle and choke tube is 2.65 ft (0.81 m). See also Reference 8.

Side Branch Accumulators Liquid-filled, quarter-wavelength, side branch accumulators reduce pulsations in a narrow frequency band and can be effective on constant/speed positive displacement pumps. However, in variable-speed systems, accumulators with or without a bladder can be made more effective by partially charging them with a gas (nitrogen or air) because the gas charge cushions hydraulic shocks and pulsations. If properly selected, located, tuned, and charged, a wide variety of accumulators (weight- or spring-loaded; gas-charged) can be used in positive displacement pump systems to prevent cavitation and waterhammer, damp pulsations, and reduce pressure surges.^{9,10} Improper sizing or location can aggravate existing problems or cause additional ones. Typically, the best location for accumulators is as close to the pump as possible.

Gas-charged dampeners, or accumulators, such as those depicted in Figure 6, are most commonly used and can be quite effective in controlling pulsations. These devices are commercially available from several sources. Their location and volume and the pressure of the charge are important to their effectiveness. When gas-charged dampeners are used, the gas pressure must be monitored and maintained because the gas can be absorbed into the liquid. The system pressure can sometimes be lower than the gas charging pressure, such as on start-up; therefore, a valve should be installed to shut off the accumulator during start-up to eliminate gas leakage to the primary liquid. When the valve is closed, the accumulator is decoupled from the system and is not effective. Accumulators with integral check valves should be adjusted so pressure transients do not close the check valve and render the accumulator ineffective. Accumulators that have bladders (Figures 6b, d, and e) to separate the gas charge from the liquid have some distinct advantages, particularly if gas absorption is a problem. Accumulators with flexible bladders must be carefully maintained because failure of a bladder could release gas into the liquid system and could compromise the effectiveness of the dampener.

The in-line gas dampener (refer to Figure 6e) has a cylinder around the pipe containing a gas volume and bladder. The liquid enters the dampener through small holes in the circumference of the pipe and impinges upon the bladder, which produces the same acoustic effect as a side branch configuration.

It is not always possible to design effective pulsation control systems using simplified techniques. For complicated piping systems with multiple pumps, an electroacoustic

FIGURE 6 Types of accumulators: (a) piston, (b) diaphragm, (c) gas-charged, (d) bladder, (e) in-line

FIGURE 7 Effect of acoustic filter on pulsations

analog¹ is recommended for designing optimum filters or accumulators. This tool has become widely accepted for designing reliable piping systems for reciprocating liquid pumps and gas compressor units. The reduction in pulsations in a liquid pump system in a nuclear plant is shown in Figure 7. These results were obtained with a two-volume acoustic filter system designed with the electroacoustic analog. The volume diameter was 19.3 in (49 cm), and the length was 4 ft (1.2 m). The choke tube diameter was 0.8 in (2 cm), and its length was 7 ft (2.1 m). The speed of the triplex (2-cm) pump was 360 rpm, and the filter resonant frequency was set at 8.1 Hz for a velocity of sound of 4550 ft/s (1390 m/s).

Piping Vibrations When mechanical resonances are excited by pulsations, vibrations in the pump and piping can sometimes be 20 times higher than under off-resonant conditions. When the mechanical resonances coincide with the acoustic resonances, an additional amplification factor as high as 300 can be encountered.

Piping system mechanical natural frequencies can be calculated using simplified design procedures to provide effective detuning from known excitation sources. A nomogram (see Figure 8) for calculating the lowest natural frequency of uniform steel piping spans¹¹ can be used in designing piping systems and in diagnosing and solving vibration problems. For example, welded between two bottles, a 4-in (102-mm) pipe that is 10 ft (3 m) long and has an inner diameter of 3.826 in (97.18 mm) would have a mechanical frequency of 74 Hz. If the pipe was an equal-leg L bend ($L = 5$), the natural frequency would be 50 Hz.

To minimize piping vibration problems, all unnecessary bends (considering routing and thermal flexibility) should be eliminated because they provide a strong coupling point between pulsation excitation forces and the mechanical system. When bends are needed, use the largest enclosed angle possible and locate restraints near each bend. Piping should also have supports near all piping size reductions and at large masses (valves, accumulators, flanges, and so on). Small auxiliary piping connections (vents, drains, pressure test connections, and so on) should be designed so the mass of the valve and flange is effectively tied back to the main piping, thus eliminating relative vibration.

Diagnostics and Instrumentation The diagnosis of vibrations in positive displacement pumps should usually include dynamic pressure measurements in the cylinders and piping near the pump. These measurements can be obtained by the use of piezoelectric or strain gage pressure transducers. If cavitation or flashing is suspected, a pressure transducer capable of measuring static and large dynamic pressures should be used; even then, cavitation-produced pressure shocks may damage the transducer.

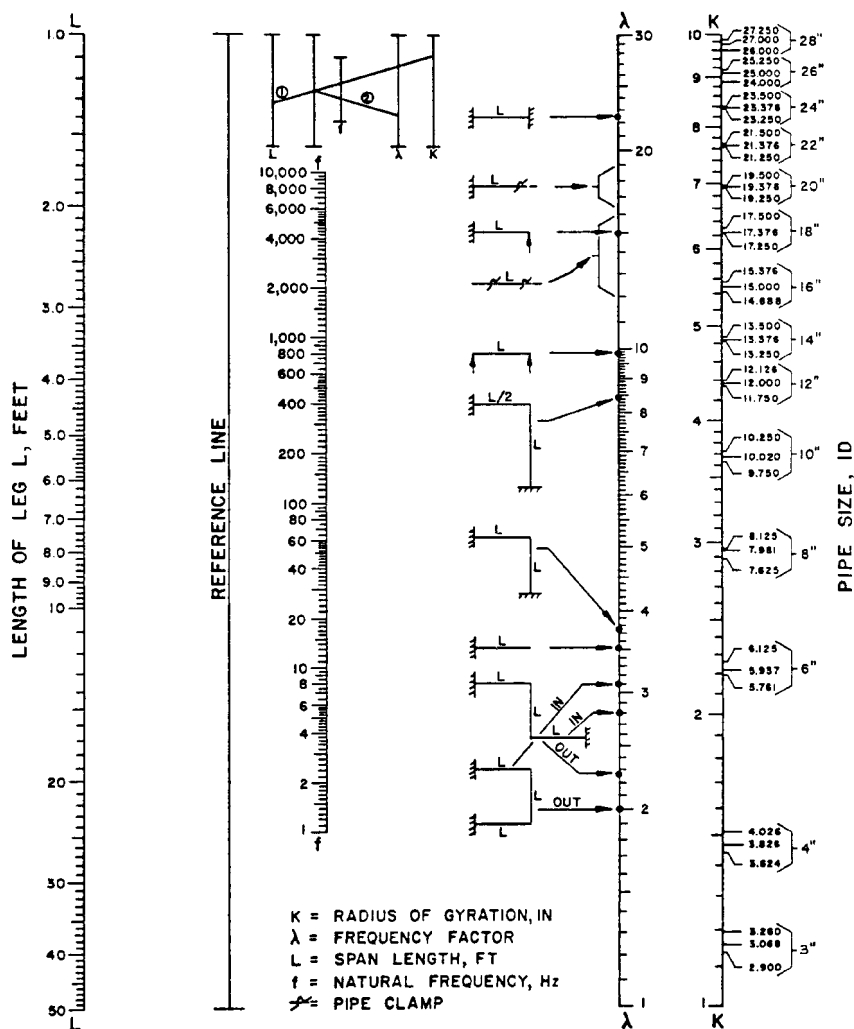

FIGURE 8 Natural frequency of uniform steel piping spans (1 ft = 0.3048 m; 1 in = 2.54 cm)

Accelerometers with low frequency characteristics may be used with electronic integrators to obtain accurate vibration displacement data from the pump case, cylinders, or piping. Similarly, velocity or seismic pickups may be employed. Maximum vibrations usually occur at the middle of piping spans and at unsupported elbows (out of plane).

Real-time analyzers and oscilloscopes may be used to display the resulting signals. A field example showing the diagnosis of cavitation at the pump suction using a strain gage diaphragm pressure transducer is given in the oscilloscope trace of Figure 9. The vapor pressure (gage) for this system was 25 lb/in² (172 kPa). Note that the negative half of the cycle is flattened when vapor pressure is reached and that very high amplitude pressure spikes are apparent. For liquids with dissolved gases, lower pulsation amplitudes can produce cavitation; however, the cavitation is usually less severe.

FIGURE 9 Complex wave data showing cavitation effects of pressure wave in a liquid piping system

FIGURE 10 Typical field data recorded on a three-plunger pump

Typical field pulsation data obtained on a three-plunger pump is shown in Figure 10, which is a frequency spectrum of the pulsations made by a real-time analyzer. Each spike represents a frequency multiple of running speed. Note that the third spike, representing the plunger frequency, has the largest amplitude; however, the components at one and two times pump speed are also significant, which means that these frequency components should be considered for pulsation control.

The vibration frequencies of the piping should be compared with pulsation frequencies to evaluate potential pulsation excitation of mechanical resonances. A check of the piping mechanical natural frequencies from the nomogram (refer to Figure 8) should be made to evaluate the possibility of a mechanical resonance. High vibrations produced by low-level pulsations at a particular frequency are indicative of a mechanical resonance, which can usually be corrected by additional piping restraints or snubbers. After the causes of the pulsations and vibrations are diagnosed, the techniques presented previously can be used to develop solutions.

Thermal Problems In pump systems with high thermal gradients, large forces and moments on the pump case can cause misalignment of the pump and its driver as well as pump case distortion resulting in vibrations, rubbing (wear), bearing failure, seal leakage, and so on. High stresses can be imposed on the piping, resulting in local yielding or damage to the piping restraints, snubbers, or support system. Misalignment problems commonly exhibit a high second-order component of the shaft vibrations. Proximity

probes can be used at the bearings to measure movement of the shaft relative to the bearing centerline.

Diagnosis of Shaft Failures Pump and driver shafting can experience high stresses during start-up and normal operation because of the uneven torque loading of the positive displacement pumping action. Shaft failures are strongly influenced by the torsional resonances of the system, which are the angular natural frequencies of the system.

Torsional vibrations can be measured using velocity-type torsional transducers that mount on a stub shaft. Alternatively, they may be gauged by measuring the gear tooth passing frequency with a magnetic transducer or proximity probe and using frequency-to-voltage converters to give the change in tooth passing frequency (the torsional vibrational velocity). Spectral analysis of these signals defines the torsional amplitudes and natural frequencies. The stresses can be calculated by using the mode shape of the specific resonant natural frequency and combining all the torsional loads. Torsional natural frequencies, mode shapes, and stresses can be calculated by using either the Holzer technique or digital computer programs.¹²

Torsional problems can usually be solved by changing the coupling stiffness between the driver and pump or by using a flywheel in an effective location. The addition of a flywheel will tend to smooth the torque oscillations. Pumps with a greater number of cylinders and equal cylinder phasing usually operate more smoothly with lower shaft stresses.

SECTION 3.5

DISPLACEMENT PUMP FLOW CONTROL

WILL SMITH

FLOW CONTROL IN INDIVIDUAL PUMPS

An inherent characteristic of positive displacement pumping of relatively incompressible liquids is that flow rate is proportional to displacement rate and independent of pressure levels. The capacity of a centrifugal pump operating at constant speed varies from a maximum flow at no developed pressure to zero flow at a definite limiting pressure known as shutoff head. The *average* capacity of positive displacement pumps at constant speed is, within design limits of pressure, practically constant, even though flow rate pulsations do occur as individual displacements are forced into the discharge pipe.

Flow control of positive displacement pumps is accomplished by

- Changing the displacement rate
- Changing the displacement volume
- Changing the proportion of the displacement delivered into the piping system

Throttle Control in Direct-Acting Steam Pumps Direct-acting pumps are controlled by speed change, which is effected by throttling the flow of steam (or other motive gas) to the drive cylinder. The magnitude of excess force on the drive piston over that required for the driven, or pumping, piston to force pumpage into the piping system dictates the stroke rate and therefore the capacity of the pump. A sensor that detects the desired result of pumping (pressure, level, flow rate, and so on) may be used to modulate the steam throttle valve.

Speed Control in Power-Driven Pumps Speed modulation is the most common means of flow control for power-driven pumps. The most rudimentary speed control is intermittent (start-stop) operation. The average capacity over relatively long time periods depends upon the percentage of time the pump operates at 100% versus the percentage of time it

operates at zero flow. Of course, consideration must be given to the frequency of starts because electric motors may overheat if there is insufficient time for cooling after the inrush of starting current.

When continuous modulation of flow is desired, means of varying the driver speed or the ratio of speed reduction between the driver and pump are employed.

DRIVER SPEED CONTROL

1. Multispeed constant-torque motors offer limited steps in speeds.
2. Variable-frequency motor controls permit a wide range of fully modulated speeds but, at present, are limited in maximum horsepower (Subsection 6.2.2).
3. Direct current and wound rotor alternating current motors permit modulation of speeds within definite limits of torque capability (Subsection 6.2.2).
4. Gasoline and diesel engines provides speed variation capabilities within the limits where driver torque is adequate to satisfy the constant-torque requirements of the pump (Subsection 6.1.3).
5. Steam or gas turbines can operate over a limited speed range within their particular output torque limits (Subsections 6.1.2 and 6.1.5).

SPEED CHANGER CONTROL Because *most* positive displacement pumps operate at significantly lower speed than *most* drivers, a speed reduction unit is coupled between driver and pump. Capacity control by varying the ratio of the speed reduction is quite convenient. A number of methods are used.

1. *Variable-ratio belt drives* change the speed by changing the pitch diameter of driver and driven sheaves in response to capacity requirements (Subsection 6.2.5).
2. *Hydraulic torque converters* (hydrodynamic drives) vary the speed by regulating the amount of active drive fluid in the coupling. Because these converters relate torque to speed, they are sensitive to the driven torque requirement change that may derive from system pressure changes (Subsection 6.2.3).
3. *Hydroviscous drives* vary the slip between input and output shafts by adjusting the distance between elements in a viscous fluid environment (Subsection 6.2.3).
4. *Eddy-current couplings* also vary the slip between driver and driven elements but do so by varying the strength of a magnetic field (Subsection 6.2.1).

Variable Displacement Flow Control Rather than by speed control (changes in the number of displacements in a given period of time), flow may be varied by changing the volume displaced per stroke.

Variable strokes are generally limited to small metering or “controlled volume” pumps. Although large-capacity variable-stroke pumps have been built, the complexity of the mechanism involved and the development of other effective and economical means of flow control have precluded their use (Subsection 9.16).

Changing Delivery to the System Another means of capacity control is *not* to vary the pump capacity but to alter the amount of pumpage delivered to the system. There are two popular means of doing this.

SUCTION VALVE UNLOADING Suction valve unloaders cause the displacement to be ineffective during the strokes for which the unloaders are activated. They command either full or zero delivery while the pump is kept running. Thus, current inrush problems from frequent motor starts are avoided. Because discharge pressure is not developed when suction valves are unloaded, energy consumption is held to a minimum.

A pump valve is unloaded by mechanically preventing the valve plate from returning to its seat. If the suction valve is held away from its seat, liquid will ebb and flow through the valve from suction header to pump cylinder and from cylinder to header during the stroking of the plunger or piston.

FIGURE 1 Synchronized unloading keeps the valve open through the use of a suction valve unloader.

FIGURE 2 "Hall effect" microprocessor distributor system.

The unloader mechanism does not move the valve. The valve is lifted off its seat by the pressure differential created by normal pump operation. In synchronized unloading, the suction valve unloader (Figure 1) is retracted only when it is certain that the incoming flow will keep the valve open.

The unloader never resists pressure in the cylinder; it merely holds the valve plate against valve springs that had already been compressed and moves away from the valve while the springs are still compressed. This permits the valve to close when the plunger begins its discharge stroke.

For smooth transition between full flow and zero flow, the unloading and loading are accomplished in an immediate and identical sequence of the pumping order of the plungers. It is the function of the synchronized suction valve unloader distributor (Figure 2) to control unloading events in that proper and immediate sequence. Similarity can be drawn to the gasoline engine distributor in its function of assuring the proper and immediate sequence of firing of the spark plugs.

The distributor is driven directly by the crankshaft so its position is positively indexed to the stroking of the plungers. It provides an electrical signal to a solenoid valve, which

admits motive fluid pressure to the unloader chamber when the suction valve to the particular cylinder has been opened. Then, in sequence, each of the remaining suction valves is retained so, in the first revolution of the pump after a control signals the distributor to initiate unloading, all suction valves are unloaded and the pump capacity is reduced to zero. When the control again signals for capacity, each suction valve is released, in sequence, during a single revolution of the crank.

While unloaded, the discharge valves do not function; they remain closed and serve as check valves against the pressurized discharge system. The suction valves remain open. Liquid enters from and is dispelled back into the suction manifold through the open suction valves. Therefore, no work is applied to the liquid, not even that required to open the suction and discharge valves. When the control calls for loading, the load is applied in steps equal to the number of plungers. Thus the pumping horsepower, as well as the liquid inertia in the pumping system, is changed in a number of steps equal to the number of plungers over the time span of one crank revolution.

The unloader consists of a spring-loaded pneumatic cylinder attached to the suction valve cover. The spring advances holding fingers that keep the valve away from its seat. Pneumatic pressure, applied through a solenoid valve in response to the distributor signal, creates a force on a piston that opposes the spring force and allows the suction valve to load (close). The system is normally arranged to fail in the unloaded position on either electrical or pneumatic pressure failure.

Distributor systems have evolved from a) direct mechanical linkages between reciprocating parts and the suction valves, to b) electromechanical interfacing, to c) electronic proximity systems, to d) a "Hall effect" sensor signaling a microprocessor. The objective of each of these systems is to cause suction valve unloader solenoids to activate or de-activate in the appropriate sequence and at the appropriate position of the plunger during the suction stroke.

BYPASS CONTROL Ultimate delivery of pumpage to the system may be controlled by a discharge-to-suction bypass valve. Pump operation is continuous, with the possibility of modulating the flow to the system by regulating the portion "bypassed" to suction. A serious disadvantage is the full power utilization and full-load wear and tear even when at zero system capacity.

Evaluation of Flow Control Options Proper selection of the means of capacity control requires consideration of system control requirements and then evaluation of the options available to satisfy those requirements.

Precision, responsiveness, and degree of modulation required may limit options. First cost, maintenance requirements, and the effect on pump operating cost should then be weighed for viable options. To evaluate the effect of operating costs, it is necessary to determine (or reasonably assume) the expected pattern of operation throughout the capacity range. For example, if practically all operation except infrequent start-ups is to be at full pump capacity, little penalty should be assigned to the full power usage of a bypass valve or to the part-load losses inherent with hydroviscous or eddy-current drives.

If smooth modulation of flow is not essential, start-stop or suction valve unloading may be the preference. If smooth modulation and considerable operation at part capacity are necessary, variable-frequency motors or variable-pitch V-belt drives may be indicated.

Table 1 and Figure 3 provide some general guidelines. Each application should be evaluated on the merits of requirements and options.

FLOW CONTROL IN COMBINED DISPLACEMENT AND CENTRIFUGAL PUMPS

Systems that involve both centrifugal and reciprocating positive displacement pumps deserve some special consideration. Centrifugal pumps are often used as suction boosters to overcome acceleration head requirements peculiar to reciprocating pumps but are rarely used to supplement flow. Some unique characteristics of each type of pump that affect the other type must be considered in the design, operation, and control or the inter-related system.

TABLE 1 Comparison of several capacity control schemes for positive displacement pumps

| Control Method | Degree of Modulation | First Cost | Operating Cost | Comments |
|-------------------------------|----------------------------------|------------|----------------|--|
| <i>Directing-acting pumps</i> | | | | |
| Steam throttle | Full: zero to 100% | Low | Low | Steam pressure required to balance liquid piston force and overcome breakaway friction. Steam volume throttled to produce desired capacity. |
| <i>Power pumps</i> | | | | |
| Start-stop | Zero or 100% | Low | Low | Limited in frequency of starts because of temperature rise from inrush. |
| Multispeed motors | Steps dependent on motor winding | Medium | Low | Cost of motor controller switch gear motors must be assessed. |
| Variable frequency | Full: zero to 100% + | High | Low | Limited by current-handling capacity of solid-state controller. |
| Direct current | Full: zero to 100% | High | Medium | Drive is torque-speed sensitive, pump is torque-pressure sensitive at all speeds. Check drive for required torque at minimum and maximum speeds. |
| Wound rotor motors | Full: zero to 100% | High | Low | Drive is torque-speed sensitive. Pump is torque-pressure sensitive at all speeds. Check drive for required torque at minimum and maximum speeds. |
| Combustion engines | Variable for limited range | High | Low | Torsional analysis required to avoid high torsional stresses. |
| Steam or gas turbines | Variable for limited range | Medium | Medium | Drive is torque-speed sensitive. Pump is torque-pressure sensitive at all speeds. Check drive for required torque at minimum and maximum speeds. |
| Hydraulic torque converter | Full: zero to 100% | High | High | Low full speed efficiency. |

TABLE 1 Comparison of several capacity control schemes for positive displacement pumps (*Continued*)

| Control Method | Degree of Modulation | First Cost | Operating Cost | Comments |
|----------------------------|----------------------|------------|-------------------|---|
| <i>Power pumps</i> | | | | |
| Hydroviscous speed control | Full: zero to 100% | High | High at part load | Efficiency proportional to capacity. Loss to heat exchanger. |
| Fluid coupling | Full: zero to 100% | Medium | High | Full-speed slip loss greater than hydroviscous. Loss to heat exchanger. |
| Magnetic (eddy) coupling | Full: zero to 100% | High | High | Full-speed slip loss. |
| Suction valve unloaders | Zero or 100% | Low | Low | Synchronization with suction stroke avoids start-stop and shock problems. |
| Bypass valve | Limited | Low | High | Uses full power at zero capacity with full valve wear. |
| Variable-pitch belt | Limited | Low | Low | Limited to belt drive horsepower. |

FIGURE 3 Relative efficiencies of speed control options.

Pertinent Positive Displacement Pump Characteristics

- 1. The discharge pressure produced is a function of the system requirement only and is independent of pump capacity.
- 2. The flow rate pulses between maximum and minimum values for each revolution of the crankshaft.

3. The pulsating flow imposes an acceleration head that adds to the net positive inlet pressure required (Section 3.1).
4. Being more energy-efficient, the positive displacement pump is normally the lead pump and the centrifugal pump is the supplement when operated in parallel.

Pertinent Centrifugal Pump Characteristics

1. The dynamic head (or pressure rise) produced is a function of pump capacity as well as of system requirements.
2. For satisfactory operation, the flow must be kept within a limited range of the best efficiency capacity (Subsection 2.3.1).
3. When used as a suction booster, the centrifugal pump must be designed so it cannot introduce air into the gas-intolerant reciprocating pump. (Gas in positive displacement pumps, like liquids in positive displacement compressors, may cause severe hydraulic and mechanical shock.)
4. Centrifugal pumps do not generate acceleration heads that impose on net positive suction head required. However, if a centrifugal pump is connected in parallel to a common suction line with a reciprocating pump, some of the system acceleration head loss from the positive displacement pump may affect the centrifugal pump.

Only two cases need to be considered: centrifugal pumps feeding (1) in series into reciprocating pumps to increase suction *NPSHA* to the reciprocating pump or (2) in parallel to augment the delivered capacity. It would be most unusual to encounter a positive displacement pump feeding into the suction of a centrifugal pump because of the high pressure that could be imposed on the centrifugal pump suction and because of the amplification of flow pulsations resulting from interaction of the characteristics of the two pumps, which could be deleterious to both pumps.

Series Operation, Suction Boost The flow rate is always determined by the positive displacement pump capacity and is independent of the centrifugal booster pump. The capacity is therefore controlled as with any positive displacement pump.

The purpose of the centrifugal pump is to supply sufficient pressure to satisfy the suction requirements of the positive displacement pump. The centrifugal pump must be sized to provide the maximum rate of flow of the positive displacement pump at a pressure high enough to meet the *NPSH* requirement of the latter.

With a flow-controlled positive displacement pump, speed control of the booster might be considered, as illustrated in Figure 4. The system pressure requirement can be satisfied by the positive displacement pump at all flow rates; therefore, total energy requirements may be reduced by using the less efficient centrifugal pump to develop no more than the required suction head.

If the centrifugal booster pump is run at constant speed, its share of the total head requirement will increase as system capacity is reduced.

Parallel Operation To increase the capacity of an existing pumping system, it is sometimes convenient to consider paralleling a positive displacement pump with a centrifugal pump. The interactions of the two pumps and the system must be considered and controlled for satisfactory operation.

Suction stabilizers and discharge dampeners, desirable for most reciprocating pump installations, become mandatory when a centrifugal pump and a positive displacement pump are connected in parallel. These devices are used to isolate, as much as possible, the effects of positive displacement pump flow pulsations from the sensitive centrifugal pump operating characteristics.

Centrifugal pumps in parallel with positive displacement pumps can supplement the system capacity only while they generate sufficient discharge pressure to satisfy the system requirement at the higher total flow. Undampened flow pulsations shift the centrifugal shutoff flow point relative to system flow at the frequency of the reciprocating

FIGURE 4 A centrifugal booster pump can satisfy the NPSH requirement of a positive displacement pump by operating either on its characteristic full speed curve 1-2-3-4 or with speed reduction along curve 1'-2'-3'-4'.

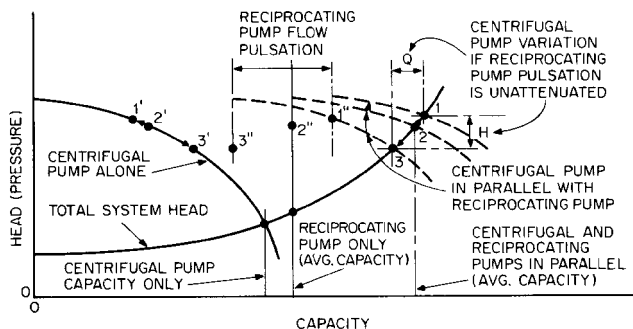

FIGURE 5 Parallel operation of undamped reciprocating and centrifugal pumps.

1. The reciprocating pump will operate at a capacity corresponding to its speed regardless of its discharge pressure.
2. If the system head is only static (constant head), the centrifugal pump capacity is constant and the system flow variation corresponds to the reciprocating pump variation.
3. If the system head is partially dynamic (as illustrated), the centrifugal pump will experience flow variations.
 - a. The flatter the centrifugal pump curve, the greater the capacity and smaller the head variations on the centrifugal pump.
 - b. The flatter the system curve, the lower the capacity and greater the head variations on the centrifugal pump.

pulsation. From the system standpoint, the total flow varies along curve 1-2-3-2-1 in Figure 5. From the centrifugal pump standpoint, it varies along its characteristic curve, 1'-2'-3'-2'-1'. The reciprocating pump operates along curve 1''-2''-3''-2''-1''.

For purely static system-head curves, the centrifugal pump theoretically would not "sense" the pulsating flow. For dynamic system heads, the centrifugal pump flow varies

contracyclically with the reciprocating pump pulsations. The magnitude of the centrifugal pump flow variation due to the positive displacement pump pulsations is a function of the system head curve, the centrifugal pump head-capacity curve, the degree of flow pulse imposed on the centrifugal pump discharge header, and the liquid bulk modulus (or compressibility).

FLOW CONTROL IN POSITIVE DISPLACEMENT PUMPS IN SERIES

Whenever positive displacement pumps are installed in series (such as for multiple-station pipeline service), some variable-capacity capability is mandatory. Otherwise, any variation in capacity between series pumps or series groups of pumps would result in disastrous interstation pressures.

The flow is determined by the first pump in the line. Subsequent pumps should be equipped with capacity controls responsive to their inlet pressures. The preferred control is a continuous-modulation type, such as variable speed, unless large reservoir capacity is available between pumps.

Recirculation from discharge to suction through a throttling bypass valve may be used, at the expense of energy, to match the delivery from downstream pumps to upstream pumps. Excessive bypass flow in relation to through flow can result in significant temperature rise of the liquid.

When downstream pump capacity is less than the upstream delivery, the inter-pump pressure will rise, indicating a need for increased capacity. When the downstream pump capacity exceeds the upstream delivery, the downstream pump will “draw down” the inter-pump pressure to the point where net positive inlet pressure difficulties are ensured.

Reservoir accumulators between pumps permit a limited degree of mismatch in capacities, allowing the use of incremental capacity controls, such as suction valve unloading and intermittent pump bypass.

In any event, effective discharge dampeners on the upstream pump and suction stabilizers on the downstream pump are necessary to prevent the inherent pressure pulsations and control modulation variances from adversely affecting operation.

FLOW CONTROL IN POSITIVE DISPLACEMENT PUMPS IN PARALLEL

Because the capacity of positive displacement pumps is virtually independent of head, there is no problem from the head-capacity characteristics in parallel operation—even for pumps of different sizes.

Particular attention to suction acceleration head requirements is necessary when more than one pump is taking suction from a common suction pipe. Because it cannot be assured that two pumps will not, at some point, have simultaneous suction strokes, the acceleration head requirements of each pump must be added for that portion of the suction line that furnishes the total flow. This suggests extra large suction lines, individual ones from the liquid source, or suction stabilizers sized for the total flow with individual outlet connections for each pump.

SECTION 3.6

DIAPHRAGM PUMPS

STEPHEN D. ABLE
ROBERT BEAN
WARREN E. RUPP

Diaphragm pumps are a class of displacement pumps featuring flexible membranes in combination with check valves that are used to move fluids into and out of pumping chamber(s). These pumps are used extensively in transfer and metering applications requiring flows of up to 300 gallons per minute (1150 liters per minute). They are quite versatile, handling a wide variety of fluids including chemicals, dry powders, food additives, glues, paints, pharmaceutical products, slurries, tailings, and wastewater. A distinguishing feature of all diaphragm pumps is the absence of seals or packing, meaning they can be used in applications requiring zero leakage. There are three main categories of diaphragm pumps: 1) mechanically driven, 2) hydraulically driven, and 3) air-operated.

MECHANICALLY DRIVEN DIAPHRAGM PUMPS

Many industries are served by mechanically driven diaphragms pumps. They are used in construction, chemical, and water treatment applications.

Construction Industry Mechanically driven diaphragm pumps are widely used in the construction industry for dewatering applications where pumps may ingest rocks or other debris. A popular make of this type of pump contains a spring on the plunger rod (see Figures 1 and 2). If the operating pressure exceeds the maximum recommended pumping pressure, the spring compresses and does not move the diaphragm. The spring can compress and thus keep a rock from being pushed through the wall of the pumping chamber or cause the drive mechanism to fail.

In single-diaphragm pumps, the pumped liquid can have a lot of inertia if the suction and discharge lines are relatively long. A simple accumulator on the suction (inlet) side of the pump enables the pump to draw liquid from the accumulator while it simultaneously draws liquid through the suction line.

FIGURE 1 Cross-section of a mechanically driven single-diaphragm pump for the construction industry (Gorman-Rupp)

FIGURE 2 Mechanically driven single-diaphragm pump, engine-powered (Gorman-Rupp)

During the discharge stroke, the accumulator can refill with liquid from the suction line. If the discharge line from the pump is relatively long, the inertia of the liquid can be great, as mentioned earlier, and can impose severe loads on the diaphragm and drive mechanism. The spring on the plunger rod can absorb some of the drive energy early in the discharge stroke and “give it back” during the latter part of the discharge stroke, greatly reducing the inertia loading on the diaphragm and drive mechanism.

Mechanically driven diaphragm pumps in the construction industry operate by a reciprocating plunger, usually secured to plates on both sides of the diaphragm. The diaphragms are customarily fabric-reinforced elastomers (usually synthetic rubbers) similar in many ways to the fabric-reinforced materials used in pneumatic tires. The diaphragms are normally molded with a convoluted section between the central clamped area and the clamped periphery. This convoluted section permits longer strokes than would be possible otherwise.

These pumps are sometimes duplexed so that the reciprocating means acts alternately on two diaphragms with one on a suction stroke, while the other is on a discharge stroke and vice versa. A connector called a *walking beam* is pivoted between two diaphragms. As one diaphragm is pushed down on a discharge stroke, the other diaphragm is simultaneously pulled up on a suction stroke. The pumping chambers with inlet and outlet check valves are manifolded together to a common inlet and a common outlet. The principle advantage of the duplex diaphragm pump is its more constant flow (two pressure pulsations per cycle).

Mechanically driven diaphragm pumps are used in the construction industry for dewatering foundations and cofferdams, as well as in sewage treatment plants for pumping lime slurries. They are normally limited to 50 ft (15.2 m) of differential head and are capable of suction lifts of as much as 25 ft (7.6 m).

Chemical and Water Treatment Industries Another type of mechanically driven diaphragm pump is used for the injection or transfer of chemicals into process streams at pressures up to 250 lb/in² (17 bar). These pumps are designed to enable the easy adjustment of their capacities, so precise volumes of chemicals can be injected. Typically, capacities can be adjusted through a 20:1 range. Injection repeatability is generally plus or minus 3%.

A wide range of chemicals can be handled. Wetted materials include PVC, PVDF, Polypropylene, 316SS, Alloy 20, and Alloy C22. Diaphragms are PTFE or PTFE with elastomeric backing. Ball type check valves are usually employed.

Applications for this type of pump include the injection of acids and bases for pH control, biocides, chlorination, coagulants, and fertilizers. There are two basic configurations for pumps in this class: *electromagnetic pumps* (solenoid) and *motor-driven pumps*.

Electromagnetic (electronic) pumps (see Figure 3) are used in a variety of low-power applications with flows from 0.026 to 26 gallons per hour (0.1 to 100 liters per hour) at pressures up to 250 lb/in² (17 bar). These metering pumps employ an electronic control circuit that pulses an electromagnet that, in turn, generates the linear motion of an armature-shaft-diaphragm assembly. Each electronic pulse results in one discharge stroke of the pump. At the end of the stroke, a set of springs returns the diaphragm assembly to its initial position, drawing more fluid into the pump chamber in preparation for the next stroke.

These pumps are inherently safe, as they can be run indefinitely in the stalled condition without damage to the pump or overpressuring most systems. An additional feature of certain electronic pumps is the regulation of pulse strength through electronic power control, which leads to smoother fluid injection. Capacity is usually controlled by adjust-

FIGURE 3 Electromagnetic diaphragm pump (Milton-Roy, subsidiary of Sundstrand Corp.)

ing the stroke rate, but the stroke length can also be adjusted. Combining these adjustments provides a wide range of outputs.

Advances in the electronic controls have led to the capability to control output manually from 4–20 mA process signals, digital pulses from external sources (such as flow meters), or serial data communications signals from computers. Yearly maintenance is recommended for low-pressure applications, but as pressures rise, diaphragms and check valves will need to be replaced more frequently.

Motor-driven, mechanically actuated diaphragm pumps are used in applications for flows from 2 to 300 gallons per hour (approximately 10 to 1000 liters per hour) again at pressures up to 250 lb/in² (17 bars). Since motor-driven, mechanically actuated diaphragm pumps are positive displacement pumps, capacities cannot be adjusted by the use of a throttling valve.

Three techniques are used in the industry to adjust motor-driven pump capacities. Some designs employ the use of a “mechanical lost motion” mechanism in which an adjustable mechanical stop interrupts the spring-loaded crosshead from following the cam for a portion of the stroke. This decreases the effective stroke length (see Figure 4). Other designs employ the use of an adjustable crank machined with a “variable eccentricity.” The adjustment of the crank’s position changes the pump’s effective stroke length (see Figure 5). The third design technique is the use of AC or DC variable speed motors.

At higher flow rates, attention should be paid to the system design to ensure the proper handling of pressure pulsations, due to the acceleration and deceleration of the process fluid in the lines. This is especially true for pumps having a mechanical lost motion configuration, due to the diaphragm’s rapid starts and stops. In the higher flow systems, pulsation dampeners are frequently employed in the discharge lines and occasionally need to be used in the suction lines to control pulsations. When discharge pressures are low, backpressure valves are employed to provide a system pressure sufficient to decelerate the fluid in the suction line at the end of every suction stroke. If the flow of the process fluid in the suction line has not stopped by the beginning of the discharge stroke, the accuracy of the injection is diminished. Yearly maintenance is recommended for low-pressure applications, but as pressures rise, diaphragms and check valves will need to be replaced more frequently.

Other Mechanically Driven Diaphragm Pumps Automotive fuel pumps are usually of the diaphragm type. The diaphragm is moved mechanically by a cam on a suction stroke

FIGURE 4 Diaphragm of a typical mechanical lost motion mechanism (Milton-Roy, subsidiary of Sundstrand Corp.)

FIGURE 5 Cross-section of a variable eccentric mechanically driven diaphragm pump (Milton-Roy, subsidiary of Sundstrand Corp.)

and is returned by a spring for the discharge stroke. Thus, the spring determines the discharge pressure and provides a nearly constant pump pressure to the carburetor regardless of the pump (engine) speed or the rate of fuel consumption. Hand-operated diaphragm pumps are used extensively as bilge pumps on sailboats where the loss of power is a major concern and hand operation is essential.

HYDRAULICALLY DRIVEN DIAPHRAGM PUMPS

Hydraulically driven diaphragm pumps are used in applications for the transfer or injection of chemicals into process streams at pressures up to 7500 lb/in² (approximately 500 bar). Because the diaphragm is pressure-balanced, the stresses in the diaphragms are low. Therefore, these pumps tend to require minimal maintenance. The pump's capacities can be adjusted to match the specific process requirement by adjusting the effective stroke length or stroking speed of the pump. Effective stroke lengths are adjusted by either a hydraulic lost motion, a mechanical lost motion, or by varying the eccentric's offset. The repeatability of the injected flow is plus or minus 1% or better.

Applications range from 0.26 to 26,000 gallons per hour (1 to 100,000 liters per hour). At flows above 26 gallons per hour (100 liters per hour), most pump models employ capacity adjustments based on variable eccentric or variable speed technology to avoid significant pressure spikes due to the rapid acceleration and deceleration of the fluid in the pipes.

As with the mechanical diaphragm pumps, a wide range of chemicals can be handled. Wetted materials include PVC, Polypropylene, PVDF, 316 SS, Alloy 20, Alloy C-22, Titanium, and Inconel. Diaphragms for pressures up to 4350 lb/in² (300 bar) are typically composed of PTFE or PTFE with an elastomeric backing. Diaphragms above 4350 lb/in² (300 bar) are typically 316 SS, Alloy C, or PEEK. Optional features include fluid temperature control jackets, diaphragm rupture detection capabilities, and remote diaphragm head designs. Typical applications include the injection of acids and bases for pH control, corrosion inhibitors, methanol, coagulants, primary process blending, process slurries, and drag reducers. Three types of liquid ends are used: the disc diaphragm, shown in Figure 6, the tubular diaphragm in Figure 7, and the high performance diaphragm in Figure 8.

The disc diaphragm pump is equipped with process-side and suction-side restraining plates to prevent overdisplacement of the diaphragm during system upsets. When the

FIGURE 6 Diagram of a disc diaphragm pump (Milton-Roy, subsidiary of Sundstrand Corp.)

FIGURE 7 Diagram of a tubular diaphragm configuration (Milton-Roy, subsidiary of Sundstrand Corp.)

diaphragm reaches the suction-side restraining plate, the hydraulic oil pressure drops, causing the refill valve to open and replenish the oil. When the diaphragm hits the process-side restraining plate, the hydraulic pressure rises, causing the relief valve to open, venting some oil. The fluid volume between the restraining plates is typically 150% of the maximum displaced volume of the pump. Therefore, the diaphragm does not contact both restraining plates during the same stroke.

FIGURE 8 Diagram of a high performance diaphragm design (Milton-Roy, subsidiary of Sundstrand Corp.)

The tubular diaphragm configuration is a variation of the disc diaphragm design. A diaphragm shaped in the form of a tube is placed in a chamber in front of the disc diaphragm assembly. This design eliminates the process fluid flowing through the front-restraining plate, reducing viscous losses and wear in case of slurries. The chamber must be filled with a precise amount of hydraulic fluid to avoid overdisplacing the tube.

The high-performance diaphragm configuration eliminates the use of a process-side restraining plate providing the throughflow performance of a tubular design while eliminating the possibility of overdisplacing the tube during startup and maintenance. With a mechanically arming, pressure-sensitive refill valve, the hydraulic fluid can only be replenished when the diaphragm is in the most rearward position. This eliminates the possibility of overfilling the hydraulic chamber and therefore overdisplacing the diaphragm during system upsets (blocked suction or discharge lines).

Most problems with hydraulic diaphragm pumps occur due to incorrect system designs. Pressures above 9 lb/in^2 (0.6 bar) should be maintained in the pump diaphragm heads during the suction stroke to stop vapor buildups in the hydraulic or process-side cavities. Pressures at 3 lb/in^2 (0.2 bar) can be handled in some applications with modified designs and special hydraulic fluids. *NPSH* calculations should include viscous losses in the check valves and contour plates (if so equipped).

In addition, since hydraulic diaphragm pumps are reciprocating machines, acceleration losses also have to be considered. Peak acceleration/deceleration losses occur at the beginning and end of the stroke, while peak viscous losses occur at midstroke. The losses are not additive. The manufacturer should be contacted to provide guidance in performing these calculations.

As with mechanically driven diaphragm pumps, at higher flows, pulsation dampeners should be considered to ensure the proper handling of pressure pulsations due to the acceleration and deceleration of the process fluid in the lines. This is especially true for pumps having a mechanical lost motion configuration due to the diaphragm's rapid starts and stops. When discharge pressures are low, backpressure valves are employed to provide a system pressure sufficient to decelerate the fluid in the suction line at the end of every suction stroke. If the flow of the process fluid in the suction line has not stopped by the beginning of the discharge stroke, the accuracy of the injection is compromised.

AIR-OPERATED DIAPHRAGM PUMPS (AODPS)

In general, diaphragm pumps of all types are sealless, have no dynamic seals or packing, are self-priming, and have an infinitely variable flow rate and pressure rate within the pressure and capacity ranges of the pump. *Air-operated diaphragm pumps* (AODPs) can also run dry indefinitely, and the discharge can be throttled to zero flow indefinitely.

The most common types of AODPs are the double-diaphragm pumps (duplex pumps). These contain two diaphragm chambers and two flexible diaphragms. The diaphragms are connected to each other through a connecting rod and are clamped at the outer edges of the diaphragm. The shaft-connected diaphragms move in the same linear direction simultaneously. Compressed air directed to the back side of the left diaphragm moves both diaphragms to the left, while air is exhausted to the atmosphere from the back side of the right diaphragm. After completion of a stroke, an air distribution valve directs compressed air from the supply to the back side of the right diaphragm and exhausts air to the atmosphere from the left chamber. This continuous reciprocating motion, along with properly operating internal check valves, creates an alternating intake and discharge of pumped liquid into and out of each chamber that results in a nearly continuous pumping action from the combined chambers.

A diaphragm pump air motor contains an air distribution valve that shifts positions at the end of each stroke of the pump. The air distribution valve alternately directs supply air pressure to one chamber and exhausts the other. Air motors often use a two-stage valve to control the reciprocating motion of the pump (see Figure 11). The pilot valve supplies a pilot air pressure signal to the air distribution valve throughout the entire stroke of the pump, even though pressure oscillations in the pumping system may occur. The pilot valve is not connected directly to the diaphragm's connecting rod, which provides a "deadband" to prevent the power valve from erroneously shifting just after the end of each stroke. The two views contained in Figure 11 depict the position of the moving parts just before the pilot valve is moved by its contact with the diaphragm washer. Depending on its position, the pilot rod alternately pressurizes and exhausts the large end of the air distribution valve. Other valve design configurations pressurize and exhaust both ends of the air distribution valve.

The two common types of liquid check valves that are used in a diaphragm pump are the *flap valve* and the *ball valve*. A flap valve pump (see Figures 9 and 10) can handle nearly marble-sized solids. Because the discharge is from the bottom of the diaphragm chambers, the pump is ideally suited for pumping solids in suspension that may tend to settle out, particularly when the pumping rate is reduced or when the pump is shut down. The bottom outlet enables foreign matter to be easily pumped out of the chambers.

The popular air-operated, double-diaphragm pump with ball valves (see Figures 12 and 13) features the inlet at the bottom of the diaphragm chambers, and the outlet is at the top. The top discharge arrangement has the advantage of enabling air or vapors to be easily expelled from the chambers. Trapped air or vapors in pumps having bottom outlets can reduce the volumetric displacement of the pumps as the air or vapor is alternately compressed and expanded, instead of the liquid being displaced. This can be a concern in low-flow applications requiring relatively high pumping pressure and that handle viscous liquids. In higher flow applications, a sufficient turbulence is present and air or vapors mix with the pumped liquid to purge the pumping chambers of the gases.

The performance chart of a typical 2-in (51-mm) air-operated, double-diaphragm pump (see Figure 14) is similar to that of other pump types but contains air consumption rather than horsepower consumption. With a constant supply pressure of compressed air, work and energy relationships in the air chambers, as well as liquid flow losses within the pump, result in a downward sloping head-capacity curve, similar to a centrifugal pump. The following are noteworthy features of air-operated diaphragm pumps:

- With the pump shut off, there is no power consumption. Air consumption is approximately proportional to the flow rate; there is zero air consumption at a zero flow rate and maximum air consumption at a maximum flow rate. This feature enables diaphragm pumps to be used in applications where the flow rate must be varied over a wide range or from no flow to a high flow rate.

FIGURE 9 Cross-section of an air-operated double-diaphragm pump with flap check valves (Ingersoll-Rand Fluid Products)

- The pump discharge pressure remains the same for a given capacity and air inlet pressure regardless of the specific gravity of the liquid being pumped. The discharge head varies with the specific gravity of the pumped fluid, because pressure and not head is primarily maintained by the air pressure. For centrifugal pumps, the discharge pressure is directly proportional to the specific gravity of the liquid being pumped, while head is fixed at a given point on the performance curve. The supplied air pressure, pump flow rate, and *NPSH* set the discharge pressure for a given air operated pump, not the head, which is a characteristic of a centrifugal pump operated at a fixed speed.
- The *NPSH* required for an air-operated diaphragm pump is defined in the same manner as with any reciprocating pump. The *NPSH* required is determined to occur when the volumetric efficiency drops by a measurable amount (normally 3%) at a fixed speed or flow rate.

MATERIALS OF AIR-OPERATED DIAPHRAGM PUMPS

Check valves for diaphragm pumps are of three types: flap, ball, and poppet (see Figure 15). Flap valves preferably hang in a vertical position with a horizontal flow through the valves. Their principle advantage is the capability to handle large objects in suspension. Flap valves with elastomeric hinges are extensively used. Ball valves are arranged to provide a vertical flow through the valve seats. Poppet valves are usually guided by a valve stem and are spring-loaded. The poppet type of valve is not position-sensitive and can

FIGURE 10 ARO air-operated double-diaphragm pump with flap check valves (Ingersoll-Rand Fluid Products)

FIGURE 11 Cross-section of an air-operated double-diaphragm pump air motor operation (Ingersoll-Rand Fluid Products)

FIGURE 12 Cross-section of an air-operated double-diaphragm pump with ball check valves (Ingersoll-Rand Fluid Products)

operate in any orientation. Since many diaphragm pumps are used to pump abrasive slurries, the valves usually have elastomeric faces or are elastomeric balls. Large ball check valves may have metal cores covered by a thick wall of synthetic rubber. They may also be made of solid rubber, a thermoplastic elastomer, or Teflon®.

Diaphragms are customarily made of fabric-reinforced synthetic rubber, thermoplastic elastomers, or PTFE. Diaphragm materials include most of the synthetic rubbers: neoprene, Buna N, EPDM, Viton®, thermoplastic elastomers such as Hytrel® and Santoprene® as well as Teflon®. Many combinations of pump and diaphragm materials can cover a wide range of pumped products. For some solvents and aggressive acids or alkalis, Teflon® diaphragms can be used either directly or as an overlay on the conventional diaphragm.

The diaphragms in air-operated, double-diaphragm pumps are essentially balanced and act simply as membranes separating the compressed air from the product being pumped. The only unbalance occurs during the suction stroke of one diaphragm while it is being pulled by the shaft-connected other diaphragm. When the suction lift is minimal, the unbalance may be negligible.

Pump case materials include cast iron, aluminum, stainless steel, Carpenter 20, Hastelloy C, and plastics reinforced with glass or metal fibers.

APPLICATIONS OF AIR-OPERATED DIAPHRAGM PUMPS

General Diaphragm pumps are ideally suited for handling abrasive slurries because 1) the liquid velocity through the check valves and pumping chambers does not exceed the

FIGURE 13 ARO air-operated double-diaphragm pump with ball check values (Ingersoll-Rand Fluid Products)

FIGURE 14 Performance curve for a 2-in air-operated double-diaphragm pump

FIGURE 15 Three basic types of check valves

pipeline velocity and 2) the scouring and abrasions from the slurry are minimal. Because no close-fit sliding or rubbing parts exist and velocities are low, these pumps can be used for liquids with viscosities up to 50,000 SSU (11,000 cSt). Because the turbulence and mixing are minimal, they are ideally suited for shear-sensitive materials, such as latex.

Pumping Dry Powders Since diaphragm pumps can pump air as well as liquids, they are used successfully to pump dry powders. The air acts as a fluid medium for the powders in suspension, and the pump moves the air containing the suspended powder. Sometimes it is necessary to inject air into the powder to lower the apparent specific gravity and to get the powder into suspension.

Pump Controls An air pressure regulator in the compressed air supply line can control the pumping pressure. An air line valve can control the pumping rate. Thus, the pressure and capacity are easily controlled. Although air-operated diaphragm pumps are displacement pumps, they are not positive ones. The maximum pumping pressure cannot exceed the pressure of the compressed air powering the pumps. Table 1 describes the control of diaphragm pumps with the features inherent with each drive type.

Liquids Handled and Applications A variety of liquids can be handled by AODPs, yet the compatibility of pump case materials, valve materials, and diaphragms is the basic application limitation. Liquids and slurries handled by diaphragm pumps include ceramic slurry, paint, cement grout, chemicals, glue, resins, petroleum products, driller's mud, mill scale, ore concentrates, printer's ink, sewage, filter aids, latex, waste oils, wood preservatives, core washes, asphaltic coatings, bilge waste, radioactive waste, lapping compounds, porcelain frit, mine tailings, volatile solvents, coolants with metal fines, varnish, acids, coatings, soapstone slurries, explosives, lime slurries, yeast, chocolate, and wine. Typical applications of AODPs include tank and container loading and unloading, fluid filtration, spray painting, adhesive application, process mixing and batching, cutting oil, machine coolant, lubrication, sump pumping, dewatering, and waste water treatment.

LIMITATIONS AND ADVANTAGES OF AIR-OPERATED DIAPHRAGM PUMPS

This section outlines the pros and cons of AODPS. Table 1 also details the controls of the different types of pumps. The limitations of AODPs are as follows:

TABLE 1 Control of diaphragm pumps

| Feature | Electro-Magnetically Driven | Mechanically Driven | Hydraulically Driven | Air-Operated |
|--|---|---|---|--------------------------------|
| Can run dry: | Yes | Yes | Yes | Yes |
| Self-priming: | Yes | Yes | Yes | Yes |
| Discharge can be shutoff without damage: | Yes | No | Yes | Yes |
| Relief valve required: | No | Yes | Integral to pump | No |
| Flow controlled by: | Motor speed or stroke-length adjustment | Motor speed or stroke-length adjustment | Motor speed or stroke-length adjustment | Motor speed or discharge valve |

- AODPs are not practical for pumping rates above about 300 gpm (1150 ℓ/m).
- AODPs are not manufactured for operating air pressures above 125 lb/in² gauge (8.6 bar). However, some versions are available that increase the pressure ratio by 2:1 or 3:1.
- Ice formation in air motors can occur (basic to the physics of operation), but the effect can be minimized by proper application and design.
- Diaphragms have a finite life. Fluids with abrasives and higher process temperatures can limit a diaphragm's life, but many material choices are available, including Teflon[®], and several thermoplastic elastomers.

An AODP's advantages are as follows:

- They are self-priming from a dry start.
- The pumps have an infinitely variable flow rate and pressure-within-pressure and capacity ranges.
- AODPs have no dynamic seals or packing.
- They can run dry indefinitely.
- The discharge can be throttled to zero flow indefinitely.
- No air is used when the AODP is deadheaded. Electrically driven pumps will consume a significant portion of the rated power when no demand flow exists.
- AODPs are suited for use in hazardous environments (no electric power required).
- Power is used in proportion to the pumping rate.
- They can be used in confined areas without heat buildup.
- AODPs can pump abrasive slurries and solids in suspension.
- The pumps can handle viscous liquids up to 50,000 SSU (11,000 cSt).
- A minimal degradation of the viscosity of shear-sensitive materials occurs.
- They can pump dry powders in air suspension.
- No close-fit, sliding, or rotating parts come in contact with liquid.
- No bypass is required as in other displacement pumps.
- When properly maintained, there is zero leakage.
- They are simple to maintain and to repair.
- There is no bedplate and no coupling to align.
- AODPs can be used in handling aggressive chemical solutions.
- They can handle a wider range of materials than any other type of pump.

SECTION 3.7

SCREW PUMPS

J. R. BRENNAN
G. J. CZARNECKI
J. K. LIPPINCOTT
A. J. PRANG

Screw pumps are a special type of rotary positive displacement pump in which the flow through the pumping elements is truly axial. The liquid is carried between screw threads on one or more rotors and is displaced axially as the screws rotate and mesh (see Figure 1). In all other rotary pumps, the liquid is forced to travel circumferentially, thus giving the screw pump with its unique axial flow pattern and low internal velocities a number of advantages in many applications where liquid agitation or churning is objectionable.

The applications of screw pumps cover a diversified range of markets including navy, marine, and utilities fuel oil services; marine cargo; industrial oil burners; lubricating oil services; chemical processes; petroleum and crude oil industries; power hydraulics for navy and machine tools; and many others. The screw pump can handle liquids in a range of viscosities, from molasses to gasoline, as well as synthetic liquids in a pressure range from 50 to 5000 lb/in² (3.5 to 350 bar) and flows up to 8000 gal/min (1820 m³/h).

Because of the relatively low inertia of their rotating parts, screw pumps are capable of operating at higher speeds than other rotary or reciprocating pumps of comparable displacement. Some turbine-attached lubricating oil pumps operate at 10,000 rpm and even higher. Screw pumps, like other rotary positive displacement pumps, are self-priming and have a delivery flow characteristic, which is essentially independent of pressure, provided there is sufficient viscosity in the liquid being pumped.

Screw pumps are generally classified into single- or multiple-rotor types. The latter is further divided into timed and untimed categories.

The single-screw or progressive cavity pump (see Figure 2) has a rotor thread that is eccentric to the axis of rotation and meshes with internal threads of the stator (rotor housing or body). Alternatively, the stator is made to wobble along the pump centerline.

Multiple-screw pumps are available in a variety of configurations and designs. All employ one driven rotor in a mesh and one or more sealing rotors. Several manufacturers have two basic configurations available: single-end (in Figure 3) and double-end (in Figure 4) construction, of which the latter is the better known.

FIGURE 1 Diagrams of screw and gear elements, showing (a) axial and (b) circumferential flow.

FIGURE 2 The single-screw or progressive cavity pump

FIGURE 3 Multiple-screw single-end arrangement.

As with every pump type, certain advantages and disadvantages can be found in a screw pump design. These should be recognized when selecting the best pump for a particular application. The **advantages** of a screw pump design are as follows:

- A wide range of flows and pressures
- A wide range of liquids and viscosities
- High speed capability, allowing the freedom of driver selection
- Low internal velocities
- Self-priming, with good suction characteristics
- A high tolerance for entrained air and other gases

FIGURE 4 Multiple-screw double-end arrangement.

- Low velocities for minimum churning or foaming
- Low mechanical vibration, pulsation-free flow, and quiet operation
- A rugged, compact design that is easy to install and maintain
- High tolerance to contamination in comparison with other rotary pumps

The **disadvantages** are as follows:

- A relatively high cost because of close tolerances and running clearances
- Performance characteristics sensitive to viscosity changes
- High pressure capability requires long pumping elements

THEORY

In screw pumps, it is the intermeshing of the threads on the rotors and the close fit of the surrounding housing that creates one or more sets of moving seals in a series between the pump inlet and outlet. These sets of seals or locks, as they are sometimes referred to, act as a labyrinth and provide the screw pump with its positive pressure capability. The successive sets of seals form fully enclosed cavities (see Figure 5) that move continuously from inlet to outlet. These cavities trap liquid at the inlet and carry it along to the outlet, providing a smooth flow.

Delivery Because the screw pump is a positive displacement device, it will deliver a definite quantity of liquid with every revolution of the rotors. This delivery can be defined in terms of displacement volume V_D , which is the theoretical volume displaced per revolution of the rotors and is dependent only upon the physical dimensions of the rotors. It is generally measured in cubic inches (cubic millimeters) per revolution. This delivery can also be defined in terms of theoretical capacity or flow rate Q_t measured in U.S. gallons per minute (cubic meters per hour), which is a function of displacement and speed N :

$$\text{In USC units:} \quad Q_t = \frac{V_D N}{231}$$

$$\text{In SI units:} \quad Q_t = 6 \times 10^{-8} V_D N$$

If no internal clearances existed, the pump's actual delivered or net flow rate Q would equal the theoretical flow rate. Clearances, however, do exist with the result that whenever a pressure differential occurs, there will always be internal leakage from outlet to inlet. This leakage, commonly called *slip* S , varies depending upon the pump type or

FIGURE 5 Axially moving seals and cavities. Alternate cavities filled with oil shown below. (Imo Pump)

FIGURE 6 Screw-thread proportions, showing lead, diameters, and cavity length.

model, the amount of clearance, the liquid viscosity at the pumping conditions, and the differential pressure. For any given set of these conditions, the slip for all practical purposes is unaffected by speed. The delivered flow rate or net flow rate therefore is the theoretical flow rate less the slip: $Q = Q_t - S$. If the differential pressure is almost zero, the slip may be neglected and $Q = Q_t$.

The theoretical flow rate of any pump can readily be calculated if all essential dimensions are known. For any particular thread configuration, assuming geometric similarity, the size of each cavity mentioned earlier is proportional to its length and cross-sectional area. The thread pitch measured in terms of the same nominal diameter, which is used in calculating the cross-sectional area (see Figure 6), defines the length. Therefore, the volume of each cavity is proportional to the cube of this nominal diameter, and the pump's theoretical flow rate is also proportional to the cube of this nominal diameter and the speed of rotation N (rpm):

$$Q_t = kD^3N$$

or, bringing the pitch into evidence,

$$Q_t = k_1 \times \text{pitch} \times D^2N.$$

From Figure 6, where $\text{pitch} = KD$, it follows that $k = k_1K$.

Thus, for a given geometry, it can be seen that a relatively small increase in pump size can provide a large increase in flow rate.

Slip can also be calculated,^{1,2} but usually it depends upon empirical values developed by extensive testing. These test data are the basis of the design parameters used by every pump manufacturer. Slip generally varies approximately as the square of the nominal diameter. The net flow rate therefore is

$$Q_t = kD^3N - S$$

Pressure Capability As mentioned earlier, screw pumps can be applied over a wide range of pressures, up to 5000 lb/in² (345 bar), provided the proper design is selected. Internal leakage must be restricted for high-pressure applications. Close-running clearances and high accuracy of the conjugate rotor threads are requirements. In addition, an increased number of moving seals between the inlet and outlet are employed, as in classic labyrinth-seal theory. The additional moving seals are obtained by a significant increase in the length of the pumping elements for a given size of rotor and pitch. Here the minimum pump length is sacrificed in order to gain pressure capability.

The internal leakage in the pumping elements resulting from the differential pressure between the outlet and inlet causes a pressure gradient across the moving cavities. The gradient is approximately linear (see Figure 7) when measured at any instant. Actually, the pressure in each moving cavity builds up gradually and uniformly from inlet to outlet pressure as the cavities move toward the outlet. In effect, the pressure capability of a screw pump is limited by the allowable pressure rise across any one set of moving seals. This pressure rise is sometimes referred to as *pressure per closure* or *pressure per lock* and generally is of the order of 125 to 150 lb/in² (8.6 to 10.3 bar) with normal running clearances, but it can go as high as 500 lb/in² (35 bar) when minimum clearances are employed.

Design Concepts The pressure gradient in the pump elements of all the types of screw pumps produces various hydraulic reaction forces. The mechanical and hydraulic techniques employed for absorbing these reaction forces are among the fundamental differences in the types of screw pumps produced by various manufacturers. Another fundamental difference lies in the method of engaging, or meshing, the rotors and maintaining the running clearances between them. Two basic design approaches are used:

- The *timed rotors* approach relies upon an external means for phasing the mesh of the threads and for supporting the forces acting on the rotors. In this concept, theoretically, the threads do not come into contact with each other or with the housing bores in which they rotate (refer to Figure 4).
- The *untimed rotors* approach relies on the precision and accuracy of the screw forms for the proper mesh and transmission of rotation. They utilize the housing bores as journal bearings supporting the pumping reactions along the entire length of the rotors (refer to Figure 3).

FIGURE 7 Pressure gradient along a screw set.

Timed screw pumps require separate timing gears between the rotors and separate support bearings at each end to absorb the reaction forces and maintain the proper clearances. Untimed screw pumps do not require gears or external bearings and thus are considerably simpler in design.

CONSTRUCTION

Basic Types As indicated in the introduction, three major types of screw pumps exist:

- Single-rotor
- Multiple-rotor timed
- Multiple-rotor untimed

The second and third types are available in two basic arrangements, single-end and double-end. The double-end construction (see Figure 8) is probably the best-known version, as it has been by far the most widely used for many years because of its relative simplicity and compactness of design.

Double-End Screw Pumps The double-end arrangement is basically two opposed, single-end pumps or pump elements of the same size with a common driving rotor that has an opposed, double-helix design with one casing. As can be seen from Figure 8, the fluid enters a common inlet with a split flow going to the outboard ends of the two pumping elements and is discharged from the middle or center of the pump elements. The two pump elements are, in effect, pumps connected in parallel. The design can also be provided with a reversed flow for low-pressure applications. In either of these arrangements, all axial loads on the rotors are balanced, as the pressure gradients in each end are equal and opposite.

The double-end screw pump construction is usually limited to low- and medium-pressure applications, with 400 lb/in² (28 bar) being a good practical limit to be used for planning purposes. However, with special design features, applications up to 1400 lb/in² (97 bar) can be handled. Double-end pumps are generally employed where large flows are required or where very viscous liquids are handled.

Single-End Screw Pumps All three types of screw pumps are offered in the single-end construction. As pressure requirements in many applications have been raised, the sin-

FIGURE 8 Double-end pump. Flow path provides axial balance. (Imo Pump)

FIGURE 9 Increasing pump pressure capability by modular design (Imo Pump).

FIGURE 10 Single-rotor pump. (Robbins-Meyers)

gle-end design has come into much wider use because it provides the only practical means for obtaining the greatest number of moving seals necessary for high-pressure capabilities. The main penalties of the single-end pump are the requirement and complexity of balancing the axial loads.

The single-end construction is most often employed for handling low-viscosity fluids at medium-to-high pressures or hydraulic fluids at very high pressures. The single-end design for high pressures is developed by literally stacking a number of medium-pressure, single-end pumping elements in a series within one pump casing (see Figure 9). The single-end construction also offers the best design arrangement for quantity manufacturing.

Special mention must be made of the single-end, single-rotor design (see Figure 10). The pump elements of this design consist of only a stator and one rotor. The stator has a

FIGURE 11 Axial balancing of power and idler rotors.

FIGURE 12 Double-end internal gear design. (Flowservice Corporation)

double-helix internal thread and is constructed of hard chrome stainless or tool steel material. One version of this design uses internally developed pressure in the pump to compress the elastomeric stator on the rotor, thus maintaining minimum running clearances.

In most single-end designs, special axial balancing arrangements must be used for each of the rotors, and, in this respect, the design is more complicated than the double-end construction. For smaller pumps, strictly mechanical thrust bearings can be used for differential pressures up to 150 lb/in^2 (10.3 bar), while hydraulic balance arrangements are used for higher pressures. For large pumps, hydraulic balance becomes essential at pressures above 50 lb/in^2 (3.5 bar).

Hydraulic balance is provided through the balance piston (see Figure 11) mounted on the rotors between the outlet and seal or bearing chambers, which are at inlet pressure. This piston is exposed to discharge pressure in the outlet chamber and is equal in area to the exposed area of the driven rotor threads; thus, the hydraulic forces on the rotor are canceled out.

Timed Design Timed screw pumps having timing gears and rotor support bearings are furnished in two general arrangements: internal and external. The internal version has both the gears and the bearings located in the pumping chamber and the design is relatively simple and compact (see Figure 12). This version is generally restricted to the handling of clean lubricating fluids, which serve as the only lubrication for the timing gears and bearings.

The external timing arrangement is the most popular and is extensively used. It has both the timing gears and the rotor support bearings located outside the pumping chamber (see Figure 13). This type can handle a complete range of fluids, both lubricating and non-lubricating, and, with proper materials, has good abrasion resistance. The timing gears and bearings are oil-bath-lubricated from an external source. This arrangement

FIGURE 13 Double-end external gear design. (Warren)

requires the use of four stuffing boxes or mechanical seals, as opposed to the internal type, which employs only one shaft seal.

The main advantage of the timed screw pump is that the timing gears transmit power to the rotors with no contact between the screw threads, thus promoting long pump life. The gears and rotors are timed at the factory to maintain the proper clearance between the screws. With certain designs and loading characteristics, the bearings at each end of the rotating elements can support the rotors so that they do not come in contact with the housing; hence, no liner is required. One set of these bearings also positions and supports the timing gears. Under more heavily loaded conditions, the body bores act as sleeve bearings and provide additional support for the rotors.

The timing gears can be either spur or helical, herringbone, hardened-steel gears with tooth profiles designed for efficient, quiet, positive drive of the rotors. Antifriction radial bearings are usually of the heavy-duty roller type, while the thrust bearings, which position the rotors axially, are either double-row, ball-thrust or spherical-roller types.

The housing can be supplied in a variety of materials, including cast iron, ductile iron, cast steel, stainless steel, and bronze. In addition, the rotor bores of the housing can be lined with industrial hard chrome for abrasion resistance.

Since the rotors are not generally in metallic contact with the housing or with one another, they can also be supplied in a variety of materials, including cast iron, heat-treated alloy steel, stainless steel, Monel, and nitralloy. The outside of the rotors can also be furnished with a variety of hard coating materials such as nickel-based alloys, tungsten carbide, chrome oxide, or ceramic.

Untimed Design The untimed type of screw pump has rotors that have generated mating-thread forms that enable any necessary driving force to be transmitted smoothly and continuously between the rotors without the use of timing gears. The rotors can be compared directly with precision-made helical gears with a high helix angle. This design usually employs three rotor screws with a center or driven rotor that meshes with two close-fitting sealing or idler rotors symmetrically positioned about the central axis (see Figure 14). A close-fitting housing provides the only transverse bearing support for both driven and idler rotors.

The use of the rotor housing as the only means for supporting idler rotors is a unique feature of the untimed screw pump. No outboard support bearings are required on these rotors. The idler rotors in their related housing bores are, in effect, partial journal bearings

FIGURE 14 Single-end design. (Roper).

FIGURE 15 Force diagram on rotor set.

that generate a hydrodynamic film. The key parameters of rotor size, clearance, surface finish, speed, fluid viscosity, and bearing pressure are related as in a journal bearing. Because, in this design, the screws transmit the driving torque to the idlers and because the casing bores support the rotors, the pumped fluid must have some lubricating properties. This prevents this pump design from being used in applications with any solids or abrasives in the pumpage.

Since the idler rotors are supported by the bores along their entire length, no significant bending loads are applied to them. The central driven rotor is also not subjected to any significant bending loads because of the symmetrical positioning of the idler rotors and the use of two threads on all the rotors (see Figure 15). This is quite different from the two-rotor design common to the timed type where the hydraulic forces generated in the pump create bending loads on the intermeshing pairs of screws.

In contrast to timed pumps, the untimed design, with its absence of timing gears and bearings, appears very simple, but its success depends entirely upon the accuracy and finish of the rotor threads and rotor housing bores. Special techniques and machine tools have been developed to manufacture these parts. The combination of design simplicity and manufacturing techniques has enabled this design to be used for very long rotor lengths, with a multiplicity of sealing closures, for applications up to $5,000 \text{ lb/in}^2$ (350 bar).

In special applications handling highly aerated oils, a four-rotor design is sometimes employed in the untimed type. Three idler rotors are equally spaced radially at 120° around the driven rotor. This design is not truly a positive displacement pump, and it falls outside the scope of this section.

The rotors in untimed pumps are generally made of gray or ductile iron or carbon steel. The thread surfaces are often hardened for high pressure and abrasive resistance. Flame hardening, induction hardening, and nitriding are currently used. Through-hardened tool steel or stainless steel can be used in some critical applications.

Rotor housings, or liners, are made of gray pearlitic iron, bronze, or aluminum alloy. In many instances, the bores as well as the rotors can be treated by the application of dry lubricant or toughening coatings. The pump casings are made of gray iron or ductile iron or cast steel where shock or other safety requirements demand it.

In many untimed designs, an antifriction bearing is employed on the shaft end of the driven rotor (refer to Figure 9) to provide precise shaft positioning for mechanical seal and coupling alignment. This bearing can be either an external grease-sealed bearing or an internal type with the pumped fluid providing the lubrication. The bearing also supports overhung loads with belt or gear drives.

Seals As with any rotary pump, the sealing arrangement for the shafts is important and is often critical. Every type of rotary seal has been used in screw pumps at one time or another. Except for canned or sealless arrangements, all types of pumps require at least one rotary seal on the drive shaft. The timed screw pumps with external timing and bearings require additional seals at each rotor end to separate the pumped fluid from the lubricating oil necessary for the gears and bearings.

For drive shafts, rotary mechanical seals as well as stuffing boxes or packings are used, depending on the manufacturer and/or customer preference. Double back-to-back arrangements or tandem mounted seals with a flushing liquid are sometimes used for very viscous or corrosive substances.

Many different sealing face materials such as carbon, bronze, cast iron, Ni-resist, carbides, or ceramics are used, along with different secondary elastomer seals of various materials chosen to suit the application. Balanced and non-balanced seals can also be used to handle significant pressures. In some pump designs, the seals are subjected to only the suction pressure, while in other designs the seals must seal against the full discharge pressure. In spite of these advantages, the stuffing box is still preferred by some users. The stuffing box requires regular maintenance and tightening, which many users find objectionable, but a mechanical seal failure usually results in a major shutdown.

PERFORMANCE

Performance considerations of screw pumps are closely related to applications, and so any discussion must cover both. In the application of screw pumps, certain basic factors must be considered to ensure a successful installation. These are fundamentally the same regardless of the liquids to be handled or the pumping conditions.

In most cases, the pump selection for a specific application is not difficult if all the operating parameters are known. It is often quite difficult, however, to obtain this information, particularly inlet conditions and fluid viscosity. It is a common feeling that, inasmuch as the screw pump is a positive displacement device, these items are unimportant.

In any screw pump application—regardless of design—suction lift, viscosity, and speed are inseparable. The speed of operation is dependent upon viscosity and suction lift. If a true picture of these latter two items can be obtained, the problem of making a proper pump selection becomes simpler and the selection will result in a more efficient unit.

Inlet Conditions The key to obtaining good performance from a screw pump, as with all other positive displacement pumps, lies in a complete understanding and control of inlet conditions and the closely related parameters of speed and viscosity. To ensure quiet, efficient operation, it is necessary to completely fill the moving cavities between the rotor threads with liquid as they open to the inlet, and this becomes more difficult as the viscosity, speed, or suction lift increases. It can be said that, if the liquid can be properly introduced into the rotor elements, the pump will perform satisfactorily.

It must be remembered that a pump does not pull or lift liquid into itself. Some external force must be present to push the liquid into the rotor threads initially. Normally, atmospheric pressure is the only force present, but in some applications a positive inlet pressure is available.

Naturally, the more viscous the liquid, the greater the resistance to the flow, and therefore the slower the rate of filling the moving cavities of the threads in the inlet. Conversely,

TABLE 1 Internal axial velocity limits

| Liquid | Viscosity, SSU | Velocity, ft/s (m/s) |
|-----------------|----------------|----------------------|
| Diesel oil | 32 | 30 (9) |
| Lubricating oil | 1,000 | 12 (3.7) |
| #6 fuel oil | 7,000 | 7 (2.1) |
| Cellulose | 60,000 | $\frac{1}{2}$ (0.15) |

low-viscosity liquids flow more readily and will quickly fill the rotor cavities. It is obvious that if the rotor elements are moving too fast, the filling will be incomplete and a reduction in output will result. To obtain complete filling, the rate of liquid flow into the pumping elements should always be greater than the rate of cavity travel. Table 1 lists examples of safe internal axial velocity limits found from experience by one screw pump manufacturer for various liquids and pumping viscosities with only atmospheric pressure available at the pump inlet.

It is quite apparent from Table 1 that the pump speed must be selected to satisfy the viscosity of the liquid being pumped. The internal axial velocity is directly related to the pump speed of rotation and to the screw thread lead. The lead is the advancement made along one thread during a complete revolution of the driven rotor, as measured along the axis. In other words, it is the distance traveled by the moving cavity in one complete revolution of the driven rotor. This is also referred to as *pitch* on single start screws.

Fluids and Vapor Pressure In many cases, screw pumps handle a mixture of liquids and gases, and therefore the general term *fluid* is more descriptive. Most of these fluids, especially petroleum products because of their complex nature, contain certain amounts of entrained and dissolved air or some other gas, which is released as a vapor when the fluid is subject to reduced pressures. If the pressure drop required to overcome entrance losses is sufficient to reduce the static pressure significantly, vapors are released in the rotor cavities and cavitation results.

Vapor pressure is an important fluid property, which must always be recognized and considered. This is particularly true of volatile petroleum products such as gasoline. Crude oil is an example of a volatile fluid where the vapor pressure has been overlooked in the past when applying screw pumps. The vapor pressure of a liquid is the absolute pressure at which the liquid will change to a vapor at a given temperature. A common example is that the vapor pressure of water at 212°F (100°C) is 14.7 lb/in² (1 bar). For petroleum products, as will be discussed in Subsection 9.19.1, the *true vapor pressure* (TVP) at any temperature is a function of the *Reid vapor pressure* (absolute) (RVP). RVP is determined by the ASTM Standard D-323 procedure and is quoted at 100°F (38°C). TVP at this temperature is slightly higher than the RVP.

In all screw pump applications, the absolute static pressure must never be allowed to drop below the vapor pressure of the fluid. This will prevent vaporization or cavitation. Cavitation, as mentioned previously, results when fluid vaporizes in the pump inlet because of incomplete filling of the pump elements and a reduction of pressure. Under these conditions, vapor bubbles, or voids, pass through the pump and collapse as each moving cavity moves into a domain of higher pressure. The result is noisy vibrations, the severity depending on the extent of vaporization or the incomplete filling and the magnitude of the discharge pressure. Also, an attendant reduction in output occurs. It is therefore important to be fully aware of the characteristics of entrained and dissolved air as well as of the vapor pressure of the fluid to be handled. This is particularly true when a suction lift exists.

Net Positive Suction Head The suction conditions of screw pumps are normally defined by the *Net Positive Suction Head* (NPSH) available at the pump inlet. In some cases with systems open to the atmosphere, the inlet conditions can also be defined as suc-

FIGURE 16 Relationship of hydraulic gradient, *NPSH*, and *MSLA*.

tion lift. Suction lift occurs when the total available pressure at the pump inlet is below the atmospheric pressure and is normally the result of a change in elevation and pipe friction. Since atmospheric pressure at sea level corresponds to 14.7 lb/in² (1 bar) absolute, or 30 in Hg (762 mm Hg), in a system with the suction open to the atmosphere, this is the maximum amount of pressure available for moving the fluid, and suction lift cannot exceed these figures. In practice, the available pressure is lower because some of it is used up in overcoming friction in the inlet lines, valves, and fittings. It is considered the best practice to keep the suction lift as low as possible to ensure that an adequate *NPSH* is available to fill the suction cavities of the pumping screw. In all cases, the system *NPSHA* (available) should be greater than the pump *NPSHR* (required). Figure 16 provides an example of *NPSH* with the following values:

NPSHA = ATM + reservoir liquid level - elevation head - frictional head loss + velocity head, where ATM is the atmospheric pressure expressed in the height of a column of the liquid being pumped.

$$NPSHA = \frac{C_1 h_b}{\text{sp. gr.}} + h - Z - h_f + \frac{V^2}{2g} - h_{vp}$$

$$\text{where: } C_1 = \begin{cases} 33.9/29.92 = 1.133 & \text{for USCS units} \\ 10.3/760 = 0.136 & \text{for SI units} \end{cases}$$

If the pressure at the inlet of the pump (P_g) is known, the *NPSHA* is calculated as

$$NPSHA = \frac{C_1 h_b}{\text{sp. gr.}} + \frac{C_2 P_g}{\text{sp. gr.}} + \frac{V^2}{2g} - h_{vp}$$

$$\text{where: } C_2 = \begin{cases} 2.31 & \text{for USCS units} \\ 10.20 & \text{for SI units} \end{cases}$$

If the suction pressure is a vacuum or negative gage reading, the *NPSHA* is calculated as

$$NPSHA = \frac{C_1 h_b}{\text{sp. gr.}} - \frac{C_3 h_g}{\text{sp. gr.}} + \frac{V^2}{2g} - h_{vp}$$

where: $C_2 = \begin{cases} 1.133 & \text{for USCS units} \\ 0.01360 & \text{for SI units} \end{cases}$

The maximum suction lift available is calculated as

$$MSLA = \frac{C_1 h_b}{\text{sp. gr.}} - NPSH$$

The definitions are as follows:

V = velocity, ft/s (m/s)

P_g, h_g = pressure gage readings at the pump inlet flange lb/in² (bar) gage and in Hg (mm Hg) (vac)

P_s = absolute static pressure at pump inlet, lb/in² (bar) abs

h_g, h_{sg} = static head at pump inlet, ft (m) of liquid abs or gage

Z = elevation head, ft (m) in reference to datum

h = reservoir liquid level, ft (m) in reference to datum

h_b = barometric pressure, in Hg (mm Hg) absolute

h_v, h_f = velocity head and friction head loss, ft (m)

P_{vp}, h_{vp} = liquid vapor pressure, lb/in² (bar) abs

P_{sv} = net positive inlet pressure, lb/in² (bar) abs

$NPSH$ = net positive suction head, ft (m) of liquid abs

P_f = frictional pressure loss, lb/in² (bar)

$MSLA$ = maximum suction lift available from pump, ft (m) of pumped liquid in the above equation—or in Hg (mm Hg) (vac)

sp. gr. = specific gravity of pumped liquid

The majority of screw pumps operate with suction lifts of approximately 5 to 15 in Hg (127 to 381 mm Hg). Lifts corresponding to 24 to 25 in Hg (610 to 635 mm Hg) are not uncommon, and installations can operate satisfactorily when the absolute suction pressure is much lower. In the latter cases, however, the pumps usually take the fluid from tanks under a vacuum, and no entrained or dissolved air or gases are present. Great care must be taken when selecting pumps for these applications since the inlet losses can easily exceed the net suction head available for moving the fluid into the pumping elements.

The defining of suction requirements by the user and the stating of pump suction capabilities by the manufacturer have always been complex problems. In many cases, the $NPSHA$ is difficult to predict due to changes in the fluid characteristics and the operating conditions. In addition, the $NPSH$ required by the pump is a function of many variables, such as pump design, fluid characteristics, and operating conditions. If the operating conditions can be accurately defined, the pump manufacturers can predict the $NPSHR$ and in many cases can provide pump modifications that can minimize the $NPSHR$.

To enable the pump manufacturer to offer the most economical selection and also assure a quiet installation, accurate suction conditions should be clearly stated. Specifying a lower $NPSHA$ than actually exists may result in selection of a pump that operates at a lower speed than necessary. This means not only a larger and more expensive pump, but also a costlier driver. If the $NPSHA$ is lower than stated, the outcome could be a noisy pump installation.

Many known instances of successful installations exist where screw pumps were properly selected for low $NPSHA$ conditions. Unfortunately, many other installations with equally low $NPSHAs$ exist, which are not so satisfactory. This is because proper consideration was not given at the time the pump was specified and selected to the actual suction conditions at the pump inlet. Frequently, suction conditions are given as "flooded" simply because the source feeding the pump is above the inlet. In many cases, no consideration is given to outlet losses from the tank or to pipe friction in the inlet lines, and these can be exceptionally high in the case of viscous liquids.

When it is desired to pump extremely viscous products, care should be taken to use the largest feasible size of suction piping to eliminate all unnecessary fittings and valves, and to place the pump as close as possible to the source of the supply. In addition, it may be necessary to supply the liquid to the pump under some pressure, which can be supplied by elevation, air pressure, or mechanical means. These actions will provide the maximum *NPSH* possible to the pump inlet.

Entrained and Dissolved Air As mentioned previously, a factor that must be given careful consideration is the possibility of entrained air or other gases in the liquid to be pumped. This is particularly true of installations where recirculation occurs and the fluid is exposed to air through either mechanical agitation, leaks, or improperly located drain lines.

Most liquids will dissolve air or other gases retaining them in the solution, the amount being dependent upon the liquid itself and the pressure to which it is subjected. It is known, for instance, that lubricating oils at atmospheric temperatures and pressures will dissolve up to 10 percent air by volume and that gasoline will dissolve up to 20 percent. When pressures below the atmosphere exist at the pump inlet, dissolved air will come out of the solution. Both this and the entrained air will expand in proportion to the existing partial pressure of the air (= absolute pressure minus the vapor pressure of the liquid). This expanded air will accordingly take up a proportionate part of the available volume of the moving cavities, with a consequent reduction in delivered flow rate.

One of the apparent effects of handling liquids containing entrained or dissolved gas is noisy pump operation. When such a condition occurs, it is usually dismissed as cavitation. Then too, many operators never expect anything but noisy operation from rotary pumps. This should not be the case, particularly with screw pumps. With properly designed systems and pumps, quiet, vibration-free operation can be produced and should be expected. Noisy operation is inefficient; steps should be taken to make corrections until the objectionable conditions are overcome. Correct system inlet designs and optimized pump designs with a proper speed selection can go a long way toward overcoming the problem.

In some applications, the amount of gas can be significant and can make up the majority of the fluid volume. See the later subsection on handling special multiphase applications.

Viscosity It is not often that a screw pump is called upon to handle liquids at a constant viscosity. Normally, because of temperature variations, a wide range of viscosities will be encountered. For example, a pump may be required to handle a viscosity range from 150 to 20,000 SSU, the higher viscosity usually resulting from cold-starting conditions. This is a perfectly satisfactory range for a screw pump, but a better and a more economical selection may be possible if additional information can be obtained. This information includes such things as the amount of time the pump is required to operate at the higher viscosity, whether the motor can be overloaded temporarily, whether a multi-speed motor can be used, and if the discharge pressure will be reduced during the period of high viscosity.

Quite often, only the type of liquid is specified, not its viscosity, and assumptions must be made for the operating range. For instance, Bunker C or No. 6 fuel oil is known to have a wide range of viscosity values and usually must be handled over a considerable temperature range. The normal procedure in a case of this type is to assume an operating viscosity range of 20 to 700 SSF. The maximum viscosity, however, might easily exceed the higher value if extra-heavy oil is used or if exceptionally low temperatures are encountered. If either should occur, the result may be improper filling of the pumping elements, noisy operation, vibration, and overloading of the motor.

Although it is the maximum viscosity and the expected *NPSHA* that are used to determine the size of the pump and to set the speed, it is the minimum viscosity that affects the capacity. Screw pumps must always be selected to give the specified capacity when handling the expected minimum viscosity since this is the point at which the maximum slip, and hence minimum flow rate, occurs (see Figure 17). It should also be noted that the minimum viscosity often determines the selection of the pump model because most manufacturers have special lower-pressure ratings for handling liquids having a viscosity of less than 100 SSU.

Non-Newtonian Liquids The viscosity of most liquids is unaffected by any agitation or shear to which they may be subjected as long as the temperature remains constant. These

FIGURE 17 Head-capacity (flow rate) performance curve with viscosity a parameter—for two speeds.

liquids are accordingly known as *true* or *Newtonian* liquids, for which the viscosity is constant. Another class of liquids, however, such as cellulose compounds, glues, greases, paints, starches, slurries, and candy compounds, displays changes in viscosity as agitation is varied at constant temperature. The viscosity of these substances depends upon the shear rate at which it is measured, and these fluids are termed *non-Newtonian*.

If a substance is known to be non-Newtonian, the expected viscosity under the actual pumping conditions should be determined, because it can vary quite widely from the viscosity under static conditions. Since a non-Newtonian substance can have an unlimited number of viscosity values (as the shear rate is varied), the term *apparent viscosity* is used to describe its viscous properties. The apparent viscosity is expressed in absolute units and is a measure of the resistance to the flow at a given shear rate. It has meaning only if the shear rate used in the measurement is also given.

The grease-manufacturing industry is very familiar with the non-Newtonian properties of its products, as evidenced by the numerous curves that have been published of the apparent viscosity plotted against the rate of shear. The occasion is rare, however, when one can obtain accurate viscosity information when it is necessary to select a pump for handling these products.

It is practically impossible in most instances to give the viscosity of grease in the terms most familiar to the pump manufacturer, such as Saybolt Seconds Universal or Saybolt Seconds Furol, but only a rough approximation would be of great help. For applications of this type, data taken from similar installations are most helpful. Such information should consist of the type, size, flow rate, and speed of the installed pumps; the suction pressure; the temperature at the pump inlet flange; the total working suction head; and, above all, the pressure drop in a specified length of piping. From the latter, a satisfactory approximation of the effective viscosity under the operating conditions can be obtained.

If accurate shear rate-viscosity data are available, they can be used to more accurately predict pump performance. The shear rates in various areas of the pump can be calculated to determine the viscosity changes of the liquid as it passes through the pump. In this way, the effect on suction loss, slip, and friction loss can be analyzed to help predict the *NPSH*, flow rate, and power.

Speed It was previously stated that viscosity and speed are closely tied together and that it is impossible to consider one without the other. Although rotative speed is the ultimate outcome, the basic speed that the manufacturer must consider is the internal axial velocity of the liquid going through the rotors. This is a function of pump type, design, and size.

Rotative speed should be reduced when handling liquids of high viscosity. The reasons for this are not only the difficulty of filling the pumping elements, but also the mechanical losses that result from the shearing action of the rotors on the substance handled. The

reduction of these losses is frequently of more importance than relatively high speeds, even though the latter might be possible because of positive inlet conditions.

Capacity The delivered capacity (flow) of any screw pump, as stated earlier, is the theoretical capacity less the internal leakage, or the slip, when handling vapor-free liquids. For a particular speed, $Q = Q_t - S$, where the standard unit of Q and S is the U.S. gallon per minute (cubic meter per minute).

The delivered capacity of any specific rotary pump is reduced by

- Decreasing speed
- Decreased viscosity
- Increased differential pressure

The actual speed must always be known. Most often, it differs somewhat from the rated or nameplate specification. This is the first item to be checked and verified in analyzing any pump performance. It is surprising how often the speed is incorrectly assumed and later found to be in error.

Because of the internal clearances between rotors and their housing, lower viscosities and higher pressures increase the slip, which results in a reduced flow rate for a given speed. The impact of these characteristics can vary widely for the various types of pumps. The slip, however, is not measurably affected by changes in speed and thus becomes a smaller percentage of the total flow at higher speeds. This is a significant factor in the handling of low-viscosity fluids at higher pressures, particularly in the case of untimed screw pumps that favor high speeds for the best results and best volumetric efficiency. This will not generally be the case with pumps having support-bearing speed limits.

Pump volumetric efficiency E_v is calculated as

$$E_v = \frac{Q}{Q_t} = \frac{Q - S}{Q_t}$$

with Q_t varying directly with speed. As stated previously, the theoretical capacity of a screw pump varies directly as the cube of the nominal diameter. Slip, however, varies approximately with the square of the nominal diameter. Therefore, for a constant speed and geometry, doubling the rotor size will result in an eightfold increase in theoretical flow rate and only a fourfold increase in slip. It follows therefore that the volumetric efficiency improves rapidly with increases in the rotor size.

On the other hand, viscosity changes affect the slip inversely to a certain power, which has been determined empirically. An acceptable approximation for the range of 100 to 10,000 SSU is obtained by using the 0.5 power index. Slip varies approximately with the differential pressure, and a change from 400 SSU to 100 SSU will double the slip in the same way as will a differential pressure change of 100 to 200 lb/in² (7 to 14 bar):

$$S = K \sqrt{\frac{P}{\text{viscosity}}}$$

Figure 18 shows the flow rate and volumetric efficiencies as functions of pump size.

Pressure Screw pumps do not in themselves create pressure; they simply transfer a quantity of fluid from the inlet to the outlet side. The pressure developed on the outlet side is solely the result of resistance to the flow in the discharge line. The slip characteristic of a particular pump type and model is one of the key factors that determine the acceptable operating range, and it is generally well defined by the pump manufacturer.

Power The brake horsepower (bhp), or, in SI units, the brake kilowatts, required to drive a screw pump is the sum of the theoretical liquid horsepower (kilowatts) and the internal power losses. The theoretical liquid power *tw_{hp}* (*tkW*) is the actual work done in moving the fluid from its inlet pressure condition to the outlet at the discharge pressure.

FIGURE 18 Flow rate and volumetric efficiency as functions of pump size.

Note that this work is done on all the fluid of the theoretical capacity, not just the delivered capacity, as the slip does not exist until a pressure differential DP occurs. Screw pump power ratings are expressed in terms of horsepower (550 ft-lbf/sec) in USCS units and in terms of kilowatts in SI units. The theoretical liquid horsepower (kilowatts) can be calculated as follows:

$$twhp = \frac{Q_t \Delta P}{1714} \left(tkW = \frac{Q_t \Delta P}{36} \right)$$

It should be noted that the theoretical liquid horsepower (kilowatts) is independent of the viscosity and is a function only of the physical dimensions of the pumping elements, the rotative speed, and the differential pressure.

The internal power losses are of two types: mechanical and viscous. The mechanical losses include all the power necessary to overcome the frictional drag of all the moving parts in the pump, including rotors, bearings, gears, and mechanical seals. The viscous losses include all the power lost from the fluid drag effects against all the parts in the pump as well as from the shearing action of the fluid itself. It is probable that the mechanical loss is dominant when operating at low viscosities and high speeds, and the viscous loss is the larger of these two losses at high-viscosity and slow-speed conditions.

In general, the losses for a given type and size of pump vary with the viscosity and the rotative speed and may or may not be affected by pressure, depending upon the type and

FIGURE 19 Typical overall efficiency curves.

model of pump under consideration. These losses, however, must always be based upon the maximum viscosity to be handled since they will be highest at this point.

The actual pump power output, whp (wkW), or the delivered liquid horsepower (kilowatts), is the power imparted to the liquid by the pump at the outlet. It is computed similarly to theoretical liquid horsepower (kilowatts) using Q in place of Q_t . Hence, the value will always be less. The pump efficiency E_p is the ratio of the pump power output to the brake horsepower (see Figure 19).

SPECIAL MULTIPHASE APPLICATIONS

Screw pumps have been used with gas-entrained applications for many years, but recent process changes in oil field technologies have created requirements for pumping multiphase fluids, containing more than just nominal amounts of gases. In many oil well applications, the liquid oil flow eventually degenerates into all sorts of difficult multiphase mixtures of oil, gas, water, and sand. In the past, it was common for the gas to be separated and flared off at the well head with only the liquid product to be retained for further processing. If the gas is to be processed as well, separators, compressors, and dual pipelines are required to handle the gas phase. Therefore, a pump, which can handle these difficult liquids with high gas content, can save significant equipment costs as well as operating costs. Under various conditions, the well output can vary from 100 percent liquid to 100 percent gas and all possible combinations. The applications also require the pumping equipment to be able to switch rapidly between the extremes or to handle slugs of liquid or gas, while maintaining the full discharge pressure. The timed two-screw type of pump has proven capable of pumping these multiphase products.¹

Oil well applications can include traditional on-shore sites as well as off-shore platform installations. Subsea installations are also being used to reduce the high costs of equipment and operation of traditional oil platforms. In these applications, the pumping equipment is mounted on the sea bed with piping running to on-shore gathering facilities. Although the actual pumping conditions are similar to surface installations, the installation and operating environments are far more challenging.

When pumping multiphase products with high *gas void fractions* (GVF), the pump must be designed with a small pitch to provide a sufficient number of locks. The key to

FIGURE 20 Special screw pump for multiphase applications. (Flowserve Corporation)

pumping multiphase products is to ensure that some liquid is always available to seal the screw clearances and reduce the slip. Even a small amount of recirculated liquid is sufficient to provide this seal and enable the screw pump to operate with GVF's approaching 100 percent. Depending on a number of factors, the volume of liquid required to seal and cool the screws can be three to six percent of the total inlet volume flow rate. In order to ensure that sufficient liquid is available at conditions of high GVF's, a separate liquid flush can be provided or a separator type of pump body can be used. This type of body includes a special chamber that can separate some liquid from the multiphase mixture being pumped. This liquid can be recirculated back to the screws and mechanical seals to provide sealing and cooling liquid at times when the product is almost all gas. Figure 20 shows a special screw pump designed for multiphase applications with a separating chamber built into the body.²

When pumping liquids, the slip through the internal clearances is proportional to the differential pressure and inversely proportional to the viscosity. However, in multiphase applications, as the GVF increases, the slip decreases until the inlet volume flow rate is equal to the pump displacement. This results in an almost constant inlet volume flow rate, regardless of the differential pressure. This performance can be explained by examining the pressure drop of the multiphase product across the finite clearances. This theoretical analysis confirms that a small amount of liquid in the clearances will effectively seal these clearances and reduce the slip to near zero. Figure 21 shows the typical performance characteristics for a screw pump in a multiphase application when pumping mixtures of air and water at various GVF values.³

It should be emphasized that screw pumps must be sized for the inlet volume conditions. Since the gas portion of the multiphase product is compressible, the inlet pressure and temperature conditions must be known in order to calculate the gas volume. The pump will ingest a fixed volume of product and the amount of liquid being pumped will depend on how much of this volume is being displaced by gas at the inlet to the screws.

The newest area of application for multiphase pumps is subsea. With special modifications, the rotary screw multiphase pumps can be coupled to submersible motors and mounted on the sea bed, instead of on surface platforms. The idea of pumping multiphase products directly from a subsea well head to shore facilities by means of submersible multiphase pumps has significant potential savings in separating equipment and platforms.⁴ Figure 22

FIGURE 22 Multiphase screw pump for subsea application.

shows a special, timed, two-screw pump, configured for subsea multiphase applications, with special, product-lubricated outboard bearings and pressure-compensated, lube oil chambers.

INSTALLATION AND OPERATION

Rotary pump performance and life can be improved by following the recommendations on installation and operation outlined in this section.

Pipe Size Resistance to the flow usually consists of differences in elevation, fixed resistances or restrictions such as orifices, and pipe friction. Nothing can be done about the first, since this is the basic reason for using a pump. Something can be done, however, about restrictions and pipe friction. Significant amounts of money can be wasted because of piping that is too small for the job. Certainly, not all pipe friction can be eliminated as long as fluids must be handled in this manner; but every effort should be made to use the largest pipe that is economically feasible. Numerous tables are available for calculating frictional losses in any combination of piping. Among the most recent are the tables in the

Hydraulic Institute Engineering Data Book (Reference 5) along with other similar hydraulic engineering references.

Before any new installation is made, the cost of larger-size piping, which will result in lower pump pressures, should be carefully balanced against the cost of a less expensive pump, a smaller motor, and a savings in power over the expected life of the system. The larger piping may cost a little more in the beginning, but the ultimate savings in power will often substantially offset the original cost. These facts are particularly true for extremely viscous fluids.

Foundation and Alignment The pump should be mounted on a smooth, solid foundation readily accessible for inspection and repair. It is essential that the driver shaft and the pump shaft are in proper alignment. The manufacturer's recommendation of concentricity and parallelism should always be followed and checked occasionally.

The suction pipe should be as short and straight as possible with all joints airtight. It should not contain places where air or other entrapped gases may collect. If it is not possible to have the fluid flow to the pump under gravity, a foot or check valve should be installed at the end of the suction line or as far from the pump as possible. All piping should be independently supported to avoid strains on the pump casing.

Start-Up A priming connection should be provided on the suction side, and a relief valve should be set from five to ten percent above the maximum working pressure on the discharge side. Under normal operating conditions with completely tight inlet lines and wetted pumping elements, a screw pump is self-priming. Starting the unit may involve simply opening the pump suction and discharge valves and starting the motor. It is always advisable to prime the unit before the initial startup to wet the screws. In new installations, the system may be full of air, which must be removed. If this air is not removed, the performance of the unit will be erratic, and, in certain cases, air in the system can prevent the unit from pumping. Priming the pump should preferably consist of filling not only the pump with fluid but as much of the suction line as possible.

The discharge side of the pump should be vented at startup. Venting is especially essential when the suction line is long or when the pump is initially discharging against the system pressure.

If the pump does not show a discharge of liquid after being started, the unit should be shut down immediately. The pump should then be primed and tried again. If it still does not pick up fluid promptly, there may be a leak in the suction pipe, or the trouble may be traceable to an excessive suction lift from an obstruction, throttled valve, or another cause. Attaching a gage to the suction pipe at the pump will help locate the trouble.

Once the screw pump is in service, it should continue to operate satisfactorily with practically no attention other than an occasional inspection of the mechanical seal or packing for excessive leakage and a periodic check to be certain that the alignment is maintained within reasonable limits.

Noisy Operation Should the pump develop noise after satisfactory operation, this is usually indicative of an excessive suction lift resulting from cold liquid, air in the liquid, misalignment of the coupling, or, in the case of an old pump, excessive wear.

Shutdown Whenever the unit is shut down, if the operation of the system permits, both the suction and discharge valves should be closed. This is particularly important if the shutdown is for an extended period because leakage in the foot valve, if the main supply is below the pump elevation, could drain the oil from the unit and necessitate repriming as in the initial starting of the system.

Abrasives One other point has not yet been discussed, and this is the handling of liquids containing abrasives. Since screw pumps depend upon close clearances for proper pumping action, the handling of abrasive fluids usually causes rapid wear. Much progress has been made in the use of harder and more abrasive-resistant materials for the pumping elements so that a good job can be done in some instances. It cannot be said, however,

that performance is always satisfactory when handling liquids laden excessively with abrasive materials. On the whole, screw pumps should not be used for handling fluids of this character unless a shortened pump life and an increased frequency of replacements are acceptable. In these cases, reducing the operating speed can maximize the operating life of the pump.

CONCLUDING REMARKS

As indicated, screw pumps are manufactured in a number of different configurations and designs to suit a variety of different applications. Generally, screw pumps should be considered if there is a requirement for high pressure, high viscosity, or low hydraulic pulsation levels. Screw pumps can be used with lubricating and non-lubricating products and on many special and difficult applications. The keys to the success of screw pump applications include accurate knowledge of the fluid characteristics, proper pump selection and sizing, correct system design, suitable installation conditions, and the proper operating and maintenance procedures.

SECTION 3.8

VANE, GEAR, AND LOBE PUMPS

ROBERT A. PLATT
C. W. LITTLE, JR.

DEFINITIONS AND NOMENCLATURE

Vane, gear, and lobe pumps are positive displacement rotary pumps. The Hydraulic Institute defines them as mechanisms consisting of a casing with closely fitted vanes, gears, cams, or lobes that provide a means for conveying a fluid. Their principle motion is rotating, rather than reciprocating, and they displace a finite volume of fluid with each shaft revolution. When describing them, the general term *fluid* is used, rather than the more restrictive *liquid*. Fluid, in this case, is understood to include not only true liquids, but mixtures of liquids, gases, vapors, slurries, and solids in suspension as well.

How They Work Pumping in a vane, gear, or lobe pump begins with the rotating and stationary parts of the pump defining a given volume or cavity of fluid enclosure. This enclosure is initially open to the pump inlet but sealed from the pump outlet and expands as the pump rotates. As rotation continues, the volume progresses through the pump to a point where it is no longer open to the pump inlet but not yet open to the pump outlet. It is in this intermediate stage where the pumping volume or cavity is completely formed.

Depending on the particular pump, there can be more than one cavity in existence at any one time. As this happens, fluid also fills the clearances between the pumping elements and pump body, forming a seal and lubricating the pumping elements as they in turn pump the fluid. Rotation continues and the cavities progress, moving fluid along the way. Soon a point is reached where the seal between the captured fluid volume and outlet part of the pump is breached. At this point the vanes, gears, or lobes force the volume of captured fluid out of the pump. While this is happening, other cavities are simultaneously opening at the inlet port to receive more fluid in a continual progression from suction to discharge ports.

For optimum pumping action, the *open-to-inlet* (OTI) volume should expand slowly and continuously with pump rotation. The *closed-to-inlet-and-outlet* (CTIO) pumping cavity volume should remain constant once it is formed, and the *open-to-outlet* (OTO) volume

FIGURE 1 A typical rotary gear pump

should expand slowly and continuously with pump rotation. At no time should any fluid in the pumping chambers be simultaneously open to both the inlet and outlet if the pump is truly a positive displacement pump. When these conditions are met, the result is a very smooth continuum of flow with minimal pulsations or pressure spikes.

With rotary pumps (see Figure 1), a driver turns one shaft and rotor assembly, which in turn physically meshes with another to form the cavities that move the fluid. This is known as an *untimed arrangement*. For some applications, however, there would be problems with the gears, lobes, or screws meshing this way. For instance, stainless steel gears will gall and seize if rubbed against each other. High wear rates will also occur if any dirt is trapped between the meshing lobes of a lobe pump, regardless of their material, or if a pump with meshing gears is run dry.

To circumvent this, the timed pump was developed. It uses timing gears physically located outside the pumping chamber to transmit torque between the pump shafts and synchronize the pumping elements relative to each other. By preventing them from contacting each other, they eliminate many of the problems of dirty fluids, material compatibility, and dry running. Most lobe pumps are built this way, and gear pumps can be timed or untimed as well.

In some special cases, pressure-balancing designs, relief valve arrangements, or other such considerations have led to some designs where the pump can only operate in one direction. However, the principle of operation of most rotary pumps permits them to operate equally well in either direction.

Main Components The pumping chamber of a rotary pump is the area containing the pumped fluid while the pump is operating. Fluid enters the pumping chamber through one or more inlet ports and leaves through one or more outlet ports. The body is that part of the pump that surrounds the boundaries of the pumping chamber and is also referred to as a *casing*, *housing*, or *stator*. *End plates* can either be part of the body or separate parts, and they serve to close off the ends of the body to form the pumping chamber. End plates can also be referred to as *pump covers*.

The rotating assembly generally refers to all those parts that rotate when the pump is operating. *Rotors* are usually given more descriptive names, depending on the specific pump type. All rotary pumps employ a drive shaft to accept driving torque from the pump driver. The majority of rotary pumps are mechanically coupled to their driver with various types of couplings, but sealless magnetically driven pumps have become more common in recent years.

The cavity through which the drive shaft protrudes is called the *seal chamber*, and leakage through it is controlled by a *mechanical seal* or *packing*. In a mechanical seal, two faces with opposing axial loads are maintained in close contact with each other. When compressible packing and a stuffing box are used in place of a mechanical seal and seal chamber, the packing is compressed in the stuffing box by a gland that keeps it in intimate contact with the stationary and rotating elements. A *lantern ring* or *seal cage* is often placed between two of the packing rings to enable cooling and lubrication from an external source.

A number of other auxiliary devices and arrangements can be found in vane, gear, and lobe pumps, but two are especially characteristic of these pump types. Given the positive displacing nature of these pumps, and the potentially high pressures that can result at the outlet of the pump if there is an obstruction or blockage, *safety relief valves* must be used with all positive displacement pumps. They limit the pressure by opening an auxiliary passage at a predetermined set pressure and relieving flow back to the inlet side of the pump or to the fluid's original source. They can be installed externally or serve as an integral part of the pump. One exception is flexible member pumps, which, by the nature of their design, usually do not require one, due to the resiliency and expandability of their elastomeric components.

Nonetheless, most rotary pumps are available with integral relief valves. Although these devices are a necessary investment for safety, they are not a substitute for an external system relief valve. They are a secondary safety device at best and are not intended for continuous duty, flow control, or system pressure modulation.

To reduce fluid viscosity in the pump body to facilitate a successful startup and maintain event-free operation, *heating jackets* are used. They can be either integral to the pump (either welded on or part of the body casting) or a separate bolt-on type. They are common with asphalt, gelatins, paraffin, molasses, greases, and similar fluids where, without heating, the power and torque required to drive the pump could easily overload the driver. If viscous enough, a cold startup could actually destroy the mechanical seal, shear a shaft coupling, break a drive shaft, or cause damage to the equipment some other way. Heating jackets are not intended to be the main source of heating in the system. If the system requires the fluid to be heated, some other means, such as heat tracing the system piping, must be used.

Materials of Construction When selecting materials for rotary pumps, consideration must be given to the following material properties:

- The modulus of elasticity (for deformation purposes)
- The coefficient of thermal expansion (for varying temperatures)
- The coefficient of friction (for resistance to galling when in sliding contact)

For rotary pumps with flexible members, further consideration must be given to the materials' bulk modulus for recovery from deformation.

The close running clearances of rotary pumps require that their materials resist deformation and deflection by the various forces present when the pump is operating. If they do not, then such deformation or deflection could open the clearances and lower the operating efficiency dramatically or close the clearances and cause high mechanical loading and seizing between the moving and stationary parts.

The materials must also have compatible coefficients of thermal expansion. With the potential for deflection of the rotating parts always present, the materials selected must also have good bearing characteristics to resist galling up to the point of a compressive yield of the mating materials. This is especially important when pumping low-lubricity fluids.

Furthermore, materials used for corrosion resistance in non-contacting surfaces of centrifugal pumps may be unusable in rotary pumps where the continuous sliding contact between parts can wear away their passivating or protective layers. In general, rotary material restrictions become more severe when handling low-viscosity fluids at higher pressures and/or low lubricity fluids with abrasives. In addition, even where there is no load-bearing contact between the rotating and stationary parts under normal conditions, the high transient forces generated at startup, shutdown, or any other unusual operating conditions (such as cavitation) must be considered when selecting pump materials.

The performance of flexible member pumps heavily depends on the material of the flexible member. Its bulk modulus must be high enough to keep distortion under pressure within functional limits and it must be resilient enough to spring back to its original shape after flexing or compressing. For instance, if, once deflected, the vanes in a flexible vane pump stayed that way, the pump could no longer operate. That is, these materials must be

chosen not only to satisfy the desired hydraulic conditions, but also for resistance to deterioration from fatigue, chemicals, and the temperatures to which they may be exposed.

Vane Pumps Two basic types of vane pumps exist. The most common is the rigid sliding metal vane type, and the other is the flexible or elastomeric vane used for dirty or chemically aggressive fluids. Both are based around external sliding vanes rotating about a non-concentric cam.

All rigid vane pumps have moveable sealing elements in the form of non-flexing blades, rollers, buckets, scoops, and so on. These elements move radially inward and outward by cam surfaces to maintain a fluid seal between the OTI and OTO sectors during pump operation. When the cam surface is internal to the pump body and the vanes are mounted in or on the rotor, the pump is called an *internal vane pump*. The OTI volume is defined by the body walls, the rotor walls, the fluid seal contact between the vanes, and the body. The body wall surface, the rotor surfaces, and the vane-to-rotor and vane-to-body fluid seal points define the CTIO volume. The body surface, the rotor surface, the vane-to-body fluid seal points, and the vane-to-rotor fluid seal points define the OTO volume.

In internal vane pumps, the volume behind the vanes must always be either a composite constant volume or else be vented, because of the piston-like pumping action of the vanes on the fluids trapped there. However, no such venting is required when the vanes are in the form of rocking sliders.

When the cam surface is external to the radial surface of the rotor and the vane, or the vanes are mounted in the body or stator, the pump is called an *external vane pump* and is illustrated in Figure 2. The OTI, CTIO, and OTO volumes are defined the same as for internal vane pumps when multiple external vanes are used. In this case, the rotor surface, the body surface, and the fluid seal points between them define the CTIO volume.

In addition to rigid, sliding metal vane pumps, flexible or elastomeric vane type pumps also exist. This kind of pump, illustrated in Figure 3, has a pumping action similar to that of an internal vane pump with the OTI, CTIO, and OTO volumes defined by the rotor surfaces, the body surfaces, the fluid seal contacts between the rotor flexible vanes, and the body surfaces.

The flexible liner pump in Figure 4 is similar in pumping action to the external vane pump, and all three chamber volumes of it are defined by the inner surface of the body, the outer surface of the liner, and the liquid seal contact between the liner and body bore. Most flexible liner pumps, unlike other rotary pumps, have at least one position of the rotor in which no fluid seal exists between the OTI and OTO volumes. The pump depends only on fluid velocity and inertia to limit backflow during this phase of rotation.

Vane pumps offer flows at up to 1,000 gpm (3,785 l/min) and pressures at up to 125 lb/in² (8.6 bar). They are commonly used for low-pressure transfers of gasoline, kerosene, and similar light hydrocarbons.

Gear Pumps Evidenced by drawings dating back to the 16th century, the gear pump is one of the oldest pumps of any type. It is also the most common of all rotary pumps due to the wide variety of applications it can be used in.

FIGURE 2 A typical external vane pump

FIGURE 3 Flexible vane pump

FIGURE 4 Flexible liner pump

FIGURE 5 A typical external (left) and internal (right) gear pump

Gear pumps have two gears that mesh to provide its pumping action, with one gear driving the other. The physical contact between the gears forms a part of the moving fluid seal between the inlet and outlet ports. The outer radial tips of the gears and the sides of the gears form part of the moving fluid seal between the inlet and outlet ports. The gear contact locus moves along the tooth surfaces and jumps discontinuously from tooth to tooth as the gears mesh and unmesh during rotation. These two characteristics distinguish gear pumps from lobe pumps where the rotors (lobes) are incapable of driving each other and the fluid seal contact locus between lobes moves continuously across all the radial surfaces of the lobes.

Gear pumps are classified as *external* or *internal* (see Figure 5), and external gear pumps can be either *timed* or *untimed*. External gear pumps have their gear teeth cut on their external or outside diameter and mesh about their outside diameters. Bearings support the shafts at both ends with the gears located between the bearings. This resists shaft deflection and contact between the gears and casing wall, enabling the pump to operate at higher pressures and with less overall wear over time than would otherwise be possible.

Internal gear pumps, on the other hand, have one larger gear (rotor) with gear teeth cut internally on the major diameter meshing with and driving a smaller externally cut gear (idler). Pumps of this type can be with or without a crescent-shaped partition to define the OTI, CTIO, and OTO zones.

The OTI volume of the pump chamber in gear pumps is defined by the body walls and by where each tooth tip meets and seals with the body walls as it leaves the OTI volume. The fluid trapped between the gear teeth and the body walls is sealed from both inlet and outlet chambers and is the CTIO volume. The OTO volume is defined by the body walls and the gear tooth surfaces between the fluid seal points where each tooth tip leaves the body wall and enters the OTO volume and fluid seal points where the gears mesh.

A part or all of the side (or axial) surfaces of the gears run in small-clearance contact with the axial end faces of the pumping chamber. The gear teeth run in small-clearance

contact with each other where they mesh. The tips run in small-clearance contact with the radial surfaces of the pumping chambers in their travel from the OTI to OTO volume. Load-bearing contact between the rotors or between the rotors and the stator may exist in all three of these zones, and the apertures defined by the running clearances in these zones determine the amount of slip between the OTO and OTI volumes for any given pressure difference and viscosity between them.

Both gears share pumping torque, and the proportional amount of the total torque experienced by each gear at any instant is determined by the locus of the fluid seal point between the gear teeth. As this fluid seal point moves toward the center of gear rotation, the pumping torque on that gear increases, and as the seal point moves away from the center, the torque decreases. When external timing gears are used, they transfer torque from one rotating assembly to another to safeguard against accelerated wear when dry running or handling low-lubricity or abrasive fluids.

A special form of gear pump illustrated in Figure 6 is known as a *screw-and-wheel pump*. The driving gear is helical, and the driven gear is a special form of a spur gear. The helical gear always is the driving, or power, rotor in this type of pump, and external timing gears are not used. The pumping torque in the screw-and-wheel pump is felt both by the screw and by the wheel, and the amount of torque felt by each is determined by the fluid seal contact locus points between the two rotors. As in other gear pumps, the running clearances between the rotors and between the rotors and the body walls determine leakage from the OTO volume to the OTI volume.

External gear pumps are capable of flows up to 1,500 gpm (5,680 l/min), pressures up to 500 lb/in² (34.5 bar), and viscosities up to 1,000,000 SSU (216,000 centistokes). They are found in both clean and dirty services serving the *original equipment manufacturer* (OEM), refinery, tank farm, marine, and API-related industries. Internal gear pumps are capable of flows up to 1,100 gpm (4,165 l/min), pressures up to 225 lb/in² (15.5 bar), and viscosities up to 1,000,000 SSU (216,000 centistokes). They are typically used for lower pressure transfers of fuel oils, paints, and various chemicals in the chemical processing and OEM industries.

Lobe Pumps The lobe pump receives its name from the rounded shape of the rotor radial surfaces that permits the rotors to be continuously in contact with each other as they rotate. Lobe pumps can be either single- or multiple-lobe pumps and carry fluid between their rotor lobes much in the same way a gear pump does.

Unlike gear pumps, however, neither the number of lobes nor their shape permits one rotor to drive the other, and so all true lobe pumps require timing gears. The body surfaces, rotor surfaces, the contact between rotors, and the contact between rotor lobe ends and the pump body define the OTI volume of a pump. The contact between the lobe ends and the body wall and the adjoining body wall and lobe surfaces define the CTIO volume. The body walls, rotor surfaces, lobe-to-body wall contacts, and the lobe-to-lobe contacts define the OTO volume.

FIGURE 6 A typical screw-and-wheel pump

FIGURE 7 Typical single-lobe (left) and multiple-lobe (right) pumps

FIGURE 8 A typical internal gear, or internal lobe, pump

In the two-rotor lobe pumps shown in Figure 7, the torque is shared by both rotors with the proportional amount of torque dependent on the position of the rotor-to-rotor contact point on the rotor contact locus. When the contact point is at the major locus radius (maximum lobe radius of one rotor in contact with the minimum lobe radius of an adjoining rotor), one rotor sees the full pumping torque, while the other rotor feels a balanced torque. The transfer of a full pumping torque from one rotor to the other takes place as many times in each complete revolution of a rotor as there are lobes on the rotor.

An internal lobe, or *gerotor* pump, is shown in Figure 8 and has a single rotor with a lobe-like peripheral shape. It moves in a combination of rotations and gyrations about its center of rotation in a body with internal, lobe-shaped contours in such a way that the rotor always touches the body at two or more locations to preserve the fluid seal between OTI and OTO volumes. The outer rotor surface, inner body surface, and the fluid seal points between them define the OTI volume. The outer rotor surface and the inner body surface between two adjacent fluid seal points define the CTIO volume. The outer rotor surface, inner body surface, and the rotor-to-body fluid sealing points define the OTO volume.

Most pumps of this type have one fewer rotor lobe than an internal body lobe cavity and the term *progressing tooth gear pump* is sometimes used. The full pumping torque is seen by the single rotor, but the torque is cyclic. It is a function of the position of the rotor and its sealing arrangement with the pump body, while the number of torque cycles per rotor revolution is equal to the number of lobes on the rotor.

Lobe pumps are capable of flows up to about 1,000 gpm (3,785 l/min) and pressures up to 125 lb/in² (8.6 bar). They are commonly used to pump sludge in wastewater treatment plants and in stainless steel systems for handling foodstuffs in the food, beverage, dairy, and pharmaceutical industries.

A summary of the main application advantages of vane, gear, and lobe pumps is shown in Table 1.

COMPARISONS TO CENTRIFUGAL PUMPS

A rotary pump uses mechanical and hydraulic forces to create a flow against a system backpressure. Centrifugal pumps, on the other hand, create pressure by imparting a velocity to the fluid and converting the velocity energy to a pressure energy as the fluid flows

TABLE 1 Summary of vane, gear and lobe pump attributes

| Application Advantages | | | |

around the casing and out the discharge nozzle. A comparison of the resulting performance of these two different pump types is shown in Figure 9.

The conditions of service will usually determine the best pump for an application. For instance, for constant pressure at varying flow rates, a centrifugal pump would be a good choice. An example of this is a municipal water system where consistent pressure must be maintained over a wide range in usage levels. By contrast, for a constant flow in the presence of varying back pressures, a rotary pump would be better. An example of this is an oil pipeline, where system economics dictate constant flow rates, regardless of any system pressure variations from changes in viscosity or pipe diameter.

Other differences exist between centrifugal and rotary pumps as well. The performance curves, affinity laws, and terminology used to describe rotary pumps are all different. And since rotary pumps are primarily for viscous fluids, the applications and markets

served by these two pumps are also different. One of the few direct comparisons that can be made between centrifugal and rotary pumps is with single- versus multi-stage pumps. Even here though, the analogy is not a perfect one, and certain rotary pumps, such as progressing cavity pumps, fit the description better than others. Other factors, such as vertical versus horizontal mounting, metal versus non-metallic materials, sealless and magnetically driven versus dual-containment mechanical seals and conventional drivers, are similar whether considering a centrifugal or rotary pump.

Rotary Pump Curves Centrifugal pump curves plot the flow on the X-axis with the discharge head on the Y-axis. However, rotary pumps develop the flow against a system back-pressure, rather than developing head with a corresponding flow rate. Their performance curves therefore show the flow on the Y-axis with differential pressure along the X-axis, as shown in Figure 10.

The influence of differential pressure on the flow is greatest with lower viscosity. Since this represents the worst (least) case for flow, it is the point around which the flow rate is established. Conversely, the maximum viscosity represents the worst (most) case from a power standpoint and is therefore the point around which the driver is sized.

Other considerations, such as flat versus steep curves or matching a system curve to a pump curve, also cannot be applied to rotary pumps the way they can with a centrifugal

FIGURE 10 Typical rotary pump flow and power curves (bar = psi/14.5; kW = hp \times 0.746; 50, 500, 5000 SSU = 7, 108, and 1080 centistokes respectively.)

pump. Instead, a rotary pump is selected for a given differential pressure and viscosity at the nearest commercially acceptable speed. For viscosities under 3,000 SSU (650 centistokes), this means at synchronous motor speeds with the flow rate falling at the design point or (ideally) slightly above it. For higher viscosities, rotary pumps will be run at reduced speeds, which in some cases can go well below 100 revolutions per minute (rpm).

Performance with Viscous Fluids Centrifugal pumps assume the absence of any appreciable viscous drag across the impeller shroud and vane surfaces when developing their pumping action. However, viscous drag, as the fluid passes across these surfaces, can be considerable with higher viscosities. With an increasing viscosity, an increasing amount of energy must be expended to overcome these forces and produce the same amount of hydraulic work. At some point, viscosity will simply overtake the centrifugal pump, and it can no longer overcome the inertia and viscous drag losses of the fluid. The effect of this can be seen in Figure 11.

Since rotary pumps do not work this way, they are better suited for high-viscosity fluids. Certain rotary pumps, such as twin screw pumps, can even go as high as 1,000,000 SSU (216,000 centistokes) without a significant deterioration of performance or efficiency. Compared to centrifugal pumps, rotary pumps are less efficient at lower viscosities but more efficient at higher viscosities. From an applications standpoint, this crossover point will vary from pump to pump and depends on many factors, but as a rule of thumb, it usually falls between 500 and 1,000 SSU (108 and 216 centistokes).

Affinity Laws Rotary pumps do not have a single *best efficiency point* (BEP) the way a centrifugal pump does, and no parallels for radial thrust loads exist as a function of the position on the curve relative to BEP the way there is with centrifugal pumps. Similarly, no rotary pump parameter is analogous to the specific speed (N_s) of centrifugal pumps; although, an approximate N_s -domain into which rotary pumps fall can be identified (see Chapter 1 and Section 2.1). Instead, rotary pumps simply use the flow per revolution to make general comparisons. A summary of the basic rotary pump affinity laws is shown in Table 2.

SYSTEM CONSIDERATIONS

The variety of applications and system conditions, including the vast number of fluids handled in rotary pump applications, precludes a comprehensive coverage in a handbook of this type. The best source for this information is the manufacturer of that particular pump type.

FIGURE 11 Typical efficiencies as a function of viscosity. (In this range, centistokes \approx SSU/5.)

TABLE 2 The basic affinity laws for rotary pumps

| Rotary Pump Affinity Laws For Speed | | |
|-------------------------------------|---------------------|--|
| | Speed Change | Corresponding Effect |
| | $\{RPM_2 / RPM_1\}$ | $\{GPM_2 / GPM_1\}$ |
| | $\{RPM_2 / RPM_1\}$ | no direct effect on differential pressure |
| | $\{RPM_2 / RPM_1\}$ | $\{BHP_2 / BHP_1\}$ |
| | $\{RPM_2 / RPM_1\}$ | $\{NPSH_2 / NPSH_1\}^X$ where X varies from 1.5 to 2.5 |

Mechanical Installation All rotary pumps, particularly rigid rotor pumps, must be installed so no mechanical forces other than those imposed by pump-generated pressures can act to warp or distort the pump chamber or rotating assembly. This is important because relatively small distortions of a few thousandths of an inch can cause interference between rotating and stationary parts and generate high wear rates or pump damage.

To avoid such distortions, the pump must not be installed with overly long, rigid fittings or in such a way that the pump body supports the weight of the piping system. The problem of distortion of clearances in the pump chamber is not as severe for flexible member pumps, but large mechanical forces that distort the pump body may also cause distortions of the mechanical seals and accelerate wear of the bearings. A cardinal rule, then, is that a rotary pump must not be rigidly coupled to the piping system in a way that causes it to support the weight of the piping or otherwise exposes it to any forces from thermal expansion. Poor mechanical installation is the cause of many field problems.

Dry Running Most rotary pumps will be damaged if allowed to run dry. As long as the system provides a positive static pressure on fluid present at the inlet, the pump should prime and not run dry. If a negative inlet gage pressure, or suction lift, is present at the pump inlet, the installation should be checked to ensure airtight seals throughout the entire upstream piping.

The sealing arrangement on the pump must also be checked for any leakage of air or gas into the pump through the seal. If these conditions are satisfied, fluid will enter the pump soon after pump operation starts because of the vacuum generated by pump operation. If these conditions are not met, air or other gases will flow through leaks in the inlet system or seal to satisfy the pump flow rate requirements and the pump will run dry. One safeguard to ensure fluid at the pump inlet is to install a foot valve in the submerged portion of the inlet piping. Once primed, the foot valve will keep fluid in the pump and prevent it from running dry upon subsequent restarting.

Suction Strainers Like most other pumps, rotary pumps last longer when handling clean fluids. Nonetheless, this is an ideal scenario, and the pump will more realistically encounter dirty or abrasive-laden fluids of varying degrees. Fine particles and abrasives will cause wear in the close clearances of the pump, which eventually reduces pump flow rate by increasing the slip through the increased clearances.

As such, all rotary pumps should have a suction strainer to exclude larger materials such as welding slag, scale, rust, chips, rags, bolts, nuts, and so on. Since a suction strainer contributes to suction line losses, this reduces the net inlet pressure available. The finer the filtration, the greater the restriction and the more frequently it must be maintained. This leads to a trade-off between the cost of the added maintenance versus the cost of replacing the worn pump parts earlier than they would be otherwise.

When pumping fluids over 5,000 SSU (1080 centistokes), the finest strainer screen practical is a $\frac{1}{16}$ -inch (1.5 mm) perforation. Strainers and filters not only require periodic maintenance, but should also be instrumented accordingly. It is important for the user to provide some means of monitoring, such as a differential pressure gauge or switch, since a clogged strainer will cause the pump to cavitate or even run dry.

Entrained Air and Dissolved Gases An important consideration with rotary pumps is the amount of entrained air or gas in the fluid. It is generally neglected, since a rotary pump cannot become vapor-bound the way a centrifugal pump can. Nonetheless, with entrained air present, there can be a perceived loss in the outlet flow. If the entrained air is a large enough percentage, there may be unacceptable noise and vibration levels as well.

For example, if a fluid contains five percent entrained gas by volume and the suction pressure is atmospheric, the mixture is 95 percent liquid and 5 percent gas. This mixture fills up the moving voids on the inlet side, with 5 percent of the space filled with gas and the remainder with liquid. Therefore, in terms of the amount of liquid handled, the output is reduced directly by the amount of gas present, or 5 percent. Unless this is understood up front, it could lead to a less than satisfactory output flow rate through no direct fault of the pump itself.

Entrained air is common in systems where the liquid is cycled frequently. In many cases, the foaming or air entrainment cannot be avoided, such as with the lubrication system on a large reduction gearbox. Instead, the condition must be known and well understood before selecting a pump for the application.

If dissolved gases (gases different than the fluid's own vapor) are present in the fluid, the effect on the output flow is the same as with entrained gases. This is because the dissolved gases will come out of solution when the pressure is lowered, just as the fluid's own vapor will. This will have the same net effect as the entrained gas and will occupy the available displacement capacity. Although the fluid mass transfer rate will not be affected, this is likely to be small comfort since the measured liquid displacement will be reduced.

Noise Pumps are often the most offensive noise sources in hydraulic machinery. High-pressure pulsations and heavily loaded sliding elements within the pump produce broadband, high-energy airborne noise. Vane, gear, and lobe pumps, however, are among the lowest noise producers of any fixed displacement-type pump. Flow is delivered continuously without the variations that produce noise in conventional hydraulic pumps. Pumping elements utilize a fluid film, reducing the sliding contact, and the visco-elastic properties of the fluids they pump help dampen whatever fluid-borne pressure pulsations are present. These design features are responsible for the wide use of these pumps wherever noise is critical. For instance, they are widely installed on die-casting machines, plastics equipment, presses, and an enormous variety of machine drives and machine tools.

Inlet Pressure The absolute pressure above the vapor pressure *available* at the pump inlet must always exceed the absolute pressure above the vapor pressure *required* by the pump. For rotary pumps, this pressure is determined by Hydraulic Institute standards similar to those used for centrifugal pumps.

Another consideration is the effect of a net negative total differential pressure. This can occur when there is a variable positive static pressure on the inlet that exceeds the discharge or outlet pressure. In this case, the flow slip reverses direction and actually adds

to the capacity of the pump, causing the total flow through the pump to be greater than the pump displacement capacity.

This can also occur with a stopped pump, and rotary pumps are not effective at stopping the flow through them. In applications where the flow cannot be permitted through an idle pump, or where inlet or outlet static pressure heads exist, valving in the system must be used to stop the flow. For example, in intermittent deliveries where the pump is “lifting” liquid from a source below its inlet without any valving in place to address this when the pump is stopped, the fluid will gradually drain backward through the pump and back to its source. This could create errors in measuring the amount of fluid transferred or cause the pump source (a holding tank) to overflow.

FLUID CONSIDERATIONS

Very few commercially handled fluids are homogenous liquids. In actual systems, most fluids have air or other gases dissolved or entrained in them. In other cases, solids (abrasive or non-abrasive) may be in the fluid. The variety of fluids handled by rotary pumps requires that each pump application be uniquely considered in terms of the effects of the pumped fluid on pump performance. General summaries of the effects of various fluid characteristics on pump performance are covered in the following paragraphs.

Temperature The temperature of the pumped fluid affects pump performance in three main ways. If the pump is to handle fluid at temperatures considerably different from ambient ones, the materials of construction, both in the pump and in the seals, and the operating clearances of the pump must be selected to provide the desired operating characteristics at the temperature of operation. The selection process becomes even more stringent when the pump is operated over a wide range of temperatures. Such a use may preclude the use of pump construction materials having high thermal coefficients of expansion. Furthermore, in the actual application, it may be necessary to preheat or pre-cool the pump to the operating temperature before the pump is started in order to avoid thermal shocking the internal components when the fluid enters the pump. If this is not done, the resulting rapid heating or cooling of the pump members from the inside out can damage the pump. Preheating or pre-cooling can usually be accomplished with a secondary medium such as a heating jacket.

Viscosity Another effect of fluid temperature is on the viscosity of the fluid. For the majority of the commercial liquids, the viscosity increases with decreasing temperature and decreases with increasing temperature. If the pump application requires usage over a wide temperature range, the highest viscosity at this temperature range must be known to determine whether the pump is operating below the upper speed limit imposed by this fluid viscosity. The effects of viscosity on speed and the net inlet pressure (above the vapor pressure of the liquid) required is shown in Figure 12.

Lubricity Still another important fluid characteristic is lubricity. Many rotary pumps are not designed to operate on liquids with no lubricity. Either the wear rate or the pump mechanical friction may be inefficiently high if these pumps are used on non-lubricating fluids.

Cavitation The creation of vapors and the subsequent collapse of the vapor bubbles upon reaching the higher-pressure discharge side of the pump is known as *cavitation*. Cavitation forces the liquid into the vapor voids at high velocities and produces local pressure surges of high intensities impinging on the pump surfaces. These forces can exceed the tensile strength of the metal, eroding it in the process. Left uncorrected, cavitation can cause pitting of the vanes, gears, or lobes and interior casing walls; bearing failures; and even shaft breakage. In addition, cavitation causes noise, vibration, and a loss of output flow. The bigger the pump, the greater the noise and vibration can be.

Lowering the static suction lift of a system, increasing the suction pipe diameter, and simplifying the suction piping layout can reduce cavitation by raising the net inlet pressure

FIGURE 12 How viscosity and net inlet pressure available influence flow (bar = psi/14.5. Expressed as head of pumped liquid, the net inlet pressure is called *NPSH*.)

or *NPSH* available. In reality though, the net inlet pressure available is not something that can easily be altered. Instead, the pump vendor will usually be asked to select a pump with a lower net inlet pressure required. The best way to do this is to select a larger pump running slower. This will give the fluid more residence time to fill the void on the suction side, and with larger internal passages and ports, pump entry losses will be reduced as well.

Non-Newtonian Fluids The viscosity of most fluids is unaffected by agitation or shearing as long as the temperature remains constant. They are known as *true* or *Newtonian fluids*. Certain fluids, however, change viscosity as a shear is applied at a constant temperature. The viscosity of these fluids will depend upon the shear rate at which it is measured, and these fluids are termed *non-Newtonian*. Some examples are cellulose compounds, glues, greases, paints, starches, slurries, and candy compounds.

If a fluid is non-Newtonian, the viscosity under actual pumping conditions must be determined and can vary quite a bit from the viscosity under static conditions. An example is grease, where the static viscosity is around 20,000 SSU (4300 centistokes). Under actual pumping conditions, however, the viscosity is closer to 500 SSU (108 centistokes). Without realizing this, a larger, slower pump may have been offered when a smaller, less expensive pump running at a higher speed would have been acceptable.

Tests or computations should determine the effective fluid viscosity under actual operating conditions. If the pump is to operate over a range of speed and pressures, the maximum and minimum effective viscosities over this range should be known to allow for the additional slip or horsepower that may be required and to ensure the correct operating speed and pump driver power selections. If these data are unavailable, as is often the case, then data from a similar installation can be helpful. Ideally, the information will include the pump size, flow rate, and speed as well as the *NPSH* available and the pressure drop over a specific length of piping. With this information, assumptions can be made regarding the actual viscosity.

Corrosiveness Knowledge of the corrosiveness of the pumped fluid on the pump materials in contact with the fluid is important to satisfactory pump application. The clearances in rotary pumps are small, and corrosion rates of only a few thousandths of an inch per year may seriously affect the efficiency of the pump, particularly when it is handling low-viscosity fluids. In addition, general compatibility of the fluid with the materials of pump construction must be considered. For example, a certain solvent to be pumped may soften, dissolve, or destroy the elasticity of flexible members in the pump, including those flexible members used in the sealing arrangements. Hence, the effect of the pumped fluid on the physical and chemical state of materials used in pump construction should be considered when choosing a particular application.

Abrasiveness Abrasives present a problem for every pump type, and rotary pumps are no exception. With small operating clearances, the tendency of the abrasive is to wear down and open the tight clearances of the pump. Most rotary pumps' internal clearances are long, narrow, rectangular cross sections that can be modeled as two parallel flat plates, with one plate stationary and the other moving. These clearances range from essentially zero to a few thousandths of an inch. Thus, even minor variations in manufacturing tolerances or the effects of wear over time can cause considerable variations in the percentage change of the aperture volume. Also, the movement or deflection of movable elements in the pump, when exposed to pressure differences, can cause relatively large percentage changes in these clearances in different locations within the pump.

Because rotary pumps depend upon close clearances for their pumping action, whenever abrasive or dirty fluids are encountered, accelerated wear can be expected. Wear is difficult to predict because it depends on many variables that are difficult to measure (such as particle size, size distribution, or whether smooth or jagged shaped).

Classic theory tells us that laminar slip flow Q_s between two plates follows the general equation:

$$Q_s = k \left\{ \frac{P_d \times w \times d^3}{\nu \times l} \right\} \quad (1)$$

where Q_s = slip through the clearance, gpm (m^3/hr)

k = a constant

P_d = differential pressure, lb/in^2 (bar)

w = width of clearance, in (mm)

d = clearance gap or depth, in (mm)

ν = absolute viscosity, $\text{lb}\cdot\text{sec}/\text{ft}^2$ (centipoises) [Note: (absolute viscosity in centipoises) = (kinematic viscosity in centistokes) \times sp. gr.]

l = length of clearance, in (mm)

Rotary pumps rely on close running clearances to seal between the suction and discharge pressures. This presents certain manufacturing trade-offs. For instance, the clearances must be tight enough to yield an acceptable volumetric efficiency with lower viscosities, yet large enough to facilitate internal lubrication with higher viscosities. For a given pump with a fixed viscosity and differential pressure, the slip flow is a function of the cube of the clearances only.

Unlike a centrifugal pump impeller, which can be trimmed to about 85 percent of its maximum diameter, rotary pump gears, screws, or lobes cannot be trimmed. As Figure 13 shows, up to a certain critical point, wear has little effect on the flow. Beyond this point, which varies from case to case, performance starts to deteriorate rapidly.

FIGURE 13 Output flow rate as a function of clearance size and wear

Much progress has been made in the use of harder and more abrasive-resistant materials for the pumping elements. However, rotary pumps should not be used for abrasive fluids, unless a decreased pump life and/or increased maintenance intervals are acceptable.

Other fluid characteristics could be important in the selection and application of vane, gear, and lobe pumps. Some liquids are sensitive to shear and must be handled in pumps with low shear rates. Others cannot tolerate exposure to the atmosphere, either because they can explode, crystallize, and damage the seal arrangement or otherwise interfere with the pump operation. Rotary pumps for these applications should have only static seals or multiple-section rotary seals with a protective liquid or gas in the seal zones between the fluid and outside atmosphere. In aseptic pumps, for example, stationary and moving seals can be designed with multiple seals to enable the use of steam under pressure as a sterile barrier between the pumping chamber and the atmosphere. Pumps in industrial applications where it could be dangerous if the fluid were exposed to the atmosphere may use multiple sealing arrangements with an inert liquid under pressure acting as a barrier between the pumping chamber and the outside atmosphere.

For the effective application of rotary pumps, the temperature, viscosity, lubricity, corrosiveness, and non-liquid content of the pumped fluid must be known, along with any special characteristics of the liquid, such as shear or atmospheric sensitivity. With these known, the proper pump type, seal arrangements, horsepower requirements, and speed can be determined.

Vapor Pressure A second effect of fluid temperature is on the vapor pressure of the fluid. Vapor pressure is the pressure that must be maintained at a given temperature to prevent the liquid from partially vaporizing into a gaseous state. Vapor pressure increases with temperature, and if the local pressure falls below the vapor pressure, vaporization and cavitation will occur.

Vapor pressure is particularly important when handling hydrocarbons and petrochemicals, which can have very high vapor pressures. For instance, low-sulfur crude oil vapor pressures can be as high as 100 lb/in² absolute (6.89 absolute) under summer ambient temperatures. Unless this is known when selecting a pump, the results could be a pump that works in cold weather but cavitates in warm weather.

OPERATING CHARACTERISTICS

The operating characteristics covered in this section assume the fluid is a true incompressible liquid with a viscosity independent of the rate of shear (shear strain). Common fluids used in testing are either a light lubricating oil or cool water with small amounts of soluble oil added for lubricity.

Displacement The *theoretical or geometric displacement* Q_d of a rotary pump is the total gross fluid volume transferred from the OTI volume to the OTO per unit time. A standard unit of displacement is gallons per minute (cubic meters per hour). For any given pump, the displacement depends only upon the physical dimensions of the pump elements and the pump geometry and is independent of other operating conditions. In those pumps designed for variable displacement, the pump usually is rated at its maximum displacement.

Slip Flow slip, Q_s , is an important aspect of rotary pump performance. It is defined as that quantity of fluid that slips from the OTO volume to the OTI volume per the unit of time. Slip is a function of the clearances between the rotating and stationary members, the differential pressure between the OTO volume, the OTI volume, and the fluid viscosity. Hydraulically, it is equivalent to a bypass line from the pump outlet back to the inlet. The most common unit of measuring slip is U.S. gallons per minute (cubic meters per hour).

The major slip paths through the pump in the presence of a positive differential pressure are the clearances between the end faces of the rotors and the endplates of the pump cham-

ber, and those between the outer radial surfaces of the rotors and the inner radial surfaces of the chamber. The width, length, and height of the apertures formed vary considerably with different positions of the rotor as the drive shaft turns through a complete revolution. If the differential pressure across the pump remains constant during a revolution, then the instantaneous slip rate usually varies throughout the revolution. This variation in the slip is caused by the same effect that would be produced if the physical dimensions of the equivalent bypass around the pump were varied as a function of the angular rotation of the drive shaft. This is also one of the common causes of flow pulsation in rotary pumps. It is particularly dominant when pumping low-viscosity fluids at high pressures.

The average slip for any set of operating conditions can be found by measuring the flow rate from the outlet port (assuming an incompressible liquid) and subtracting that flow rate from the theoretical displacement flow rate Q_d that would otherwise be expected at those operating conditions. Most slip paths are constant in width but may vary in height with runout of the outside diameter of the rotors or wobble of the end faces of the rotors as they rotate. The paths can also vary considerably in length with the changing positions of the rotary and body-sealing surfaces during rotation.

The effect of pressure on the slip is complex. The primary effect is direct in that slip increases in direct proportion to pressure. However, several secondary effects should be considered as well. The first is the effect of pressure differences across the pump on the dimensions of the slip path. This occurs because of the deflection of pump elements as a function of pressure. This is relatively small in rigid element pumps but can be significant in flexible vane pumps where the pressure can cause the vanes to flatten out and move away from the body walls. In addition, while the slip may increase in flexible member pumps at high pressures, in rigid rotor pumps it can actually decrease as clearances close, due to the high-pressure deflection of the rotors.

Another secondary consideration is the indirect effect of pressure on the fluid velocity through the slip paths. At any given viscosity, the flow through these paths can have the characteristics of turbulent, laminar, or slug flows. The majority of practical applications would require that the slip be a minor percentage of the pump displacement. To remain so, the velocity of fluid flow through slip paths would normally be in the laminar flow region, and the slip would then be directly proportional to the pressure difference. A pressure increase could cause a change to turbulent flow and a corresponding change in the slip as a function of pressure.

Also, an indirect effect of pressure exists on the effective compression ratio of compressible fluids. The compression ratio reduces the amount of net volume flow through the outlet port relative to the displacement of the pump. Although not a true slip in the sense discussed up to this point, the type of slip caused by this effect reduces the net volume delivered through the outlet port and consequently affects the volumetric efficiency. This effect is a secondary effect in most liquids but can become a large component of the slip in aerated or compressible liquids. An increase in the compression ratio caused by an increase in the pressure difference causes an increase in slip from this effect.

Flow Rate and Displacement The flow rate or *capacity* Q_c of a rotary pump is the net quantity of fluid delivered by the pump per the unit of time through its outlet port or ports under any given operating condition. When the fluid is incompressible, the flow rate is numerically equal to the total volume of liquid displaced by the pump per the unit of time minus the slip, all expressed in the same units. When a rotary pump is operating with zero slip, the theoretical or geometrical displacement Q_d of the pump becomes the flow rate Q_c . A common unit of flow rate is U.S. gallons per minute (cubic meters per hour):

$$Q_c = Q_d - Q_s \quad (2)$$

The theoretical displacement D per revolution (where $Q_d = ND$ and N = revolutions per unit time) can be found by integrating the differential rate of a net volume transfer over one shaft revolution with respect to the angular displacement of the drive shaft through any complete planar segment taken through the pump chamber between the inlet and outlet ports. Most pump rotors have constant radial dimensions in the axial direction in the body cavity and sweep a right circular cylinder of volume while rotating. This means

in single-rotor pumps or in multiple-rotor pumps where no sealing contact exists between rotors (all dynamic seals are formed between rotor elements and body surfaces), the volume transfer computation can be based on polar coordinates centered on each rotor axis and the contribution to the net volume transfer found for each rotor independently.

In general, the axial dimension of the rotor in the body cavity can be most simply expressed if the planar segment is taken through the rotor axis, or at least parallel to the rotor axis. Also, for most types of rotary pumps, the computation is simplified if the intersections of the plane with the body cavity occur in a CTIO region, usually midway between the inlet and outlet ports of the pump. This is particularly true for those rotary pumps that pump equally well in either direction of rotation and are generally symmetric. In many cases, the computation can be further simplified by separating the differential statement for volume transfer through the plane from the inlet to the outlet from that for volume transfer through the plane from the outlet to the inlet and expressing the results as a difference. Examples of this method of computation for some commonly used types of rotary pumps follow.

A section through a vane pump is shown in Figure 14. Let z be the axial distance toward the front endplate from the rotor end surface next to the rear endplate, and let Z be the total axial length of the rotor. Let r be the radial distance from the rotor axis. Let R_1 be the minimum radial dimension of the rotor elements at the intersection of the plane with the minor cam radius of the pump chamber in the CTIO zone. Let R_2 be the maximum radial dimension of the rotor elements at the intersection of the plane with the major cam radius of the pump chamber in the CTIO zone. Let ϕ be the angular displacement of the drive shaft (assumed to be direct-coupled to the rotor with no gear increase or decrease). Then, the general equation for D is

$$D = \int_{\phi=0}^{\phi=2\pi} \int_{r=R_1}^{r=R_2} \int_{z=0}^{z=Z} k r d\phi dr dz = k\pi Z(R_2^2 - R_1^2) \quad (3)$$

where k is a constant used to convert D to desired units ($k = 1$ if z and r are in feet and D is in cubic feet per revolution). For vanes with non-zero thickness, the actual value of D will be slightly smaller than this.

The equation describing the transition of the major radius cam surface to the minor radius cam surface is not used or needed in Equation 3, because the planar segment is entirely in the CTIO zone of the pump. Also, the integration limits for r were chosen by noting that the net volume transfer for all $r < R_1$ cancels and equals zero. The same result is obtained if the integral is expressed as the difference of the positive contribution of the integration limits 0 to R_1 .

The same computations and formula apply to flexible vane pumps with the vanes on the rotor and to any vane-in rotor pump where the surface creating the pumping action is

FIGURE 14 Displacement calculation dimensions for an internal vane pump

FIGURE 15 Displacement calculations for an external circumferential piston pump

formed on the interior surface of the body chamber. The equation can be used for most single-rotor positive displacement pumps with an appropriate selection of the numerical values for R_1 and R_2 . For example, in the vane-in-body pump, R_1 is the minimum radius of the rotor cam and R_2 is the maximum radius of the rotor cam.

An example extending this method of computing displacement to multiple-rotor pumps that have no rotor-to-rotor sealing contact is the computation on the external circumferential piston pump shown in Figure 15. A derivation can be made in the same manner used for the vane pump, and the individual equations for the net volume flow for each rotor can be computed and summed.

The pump in Figure 15 is symmetrical, and the net contribution of each rotor occurs only during a total of half of the drive shaft revolution. In the derivation shown in Equation 3, this would mean a change in the integration limits of ϕ from 2π to π for the contribution of each rotor. However, when the contributions from each of the two rotors are added, the result is the same as Equation 3.

Another method could also be used. Because of the pump symmetry, an inspection shows that two net volume components are continually transferred from the inlet to the outlet chamber by the motion of the rotors in zones A-B and E-F. One equal volume element is also continually transferred from the outlet to the inlet chamber of the cooperative action of the rotors in zone C-D. Consequently, the net volume being transferred from the outlet to inlet in zone C-D is continually canceled by one of the volumes continually being transferred from the inlet to outlet at either zone A-B or zone E-F. The entire computation then can be made only for zone A-B or zone E-F over the entire revolution. The resulting formula for displacement would be that given in Equation 3, with R_1 being the minimum radial dimension of the piston element of the rotor and R_2 being the maximum radial dimension of the piston element of the rotor.

The direct computation of displacement for multiple-rotor, positive displacement pumps where a moving seal is formed by contact between rotors is much more complex. In such pumps, the equation of motion of the locus of the contact point between rotors as a function of angular displacement of the drive shaft is needed for a rigorous solution of the displacement. The differential rate of volume transfer is not constant with angular displacement but decreases as the contact locus moves toward the inlet chamber and increases as the contact locus moves toward the outlet chamber. In this case, a graph of pump displacement versus angular displacement would not be a straight line (or constant function of angular displacement), as in the prior two examples. In effect, the motion of the contact locus superimposes a ripple on the steady-state component of the differential rate of volume transfer.

In most pumps of practical design, the peak-to-peak amplitude of the ripple is less than 10 percent of the steady-state component of displacement. Consequently, computing the peak displacement (where R_2 is the maximum radial dimension of the rotor and R_1 is half the distance between rotors of equal size) can approximate the displacement for multiple-rotor pumps with contacting rotors. The equation is given as

$$\begin{aligned} D_{av} &= 2\pi kZ \left(\frac{R_2^2}{2} + R_2 R_1 - \frac{3}{2} R_1^2 \right) \\ D_{\min} &= 4\pi kZ (R_2 R_1 - R_1^2) \\ D_{\max} &= 2\pi kZ (R_2^2 - R_1^2) \end{aligned} \quad (5)$$

If the rotors are of unequal size, the transfer rate must be computed for each rotor with R_1 taken as the radius of the pitch circle of the rotor. This also applies to gear pumps where R_1 is the radius of the pitch circle of the gears. Displacement computed by this simplified method will usually be within five percent of the true average displacement for lobe pumps and within one percent for gear pumps. For a closer approximation, Equation 5 can be used. It is precise only when the ripple waveform has a zero average component and when it is symmetric.

From a practical standpoint, pump displacement often cannot be computed precisely from the geometry of the pump and is instead established by testing. In either case, the manufacturer will usually state this because it is needed to determine the efficiency of the pump under various operating conditions.

Speed Considerations Centrifugal pumps typically run at synchronous motor speeds. The flow and head are fine-tuned by such things as trimming the impeller or underfiling the impeller vanes. Rotary pumps, on the other hand, operate with their internal dimensions fixed. Performance is usually fine-tuned externally by speed adjustments where the operating speed N is the number of revolutions of the driving or main rotor per unit time. When no gear reduction or increase exists between the drive shaft and the main rotor, the speed is measured or set at the drive shaft.

The most common unit of speed is rpm, and its direction is usually described as either clockwise or counterclockwise when viewed from the front or drive end of the pump looking at the pump shaft. The economy of manufacturing, special pressure-balancing arrangements, relief valve orientations, and other such considerations have led to some pump designs requiring that the pump operate in one direction only. However, most rotary pumps will operate equally well in either direction.

Usually, no minimum speed exists for a rotary pump, but certain vane pumps that depend on a centrifugal force to draw the vanes out of their slots do have minimum speed requirements. Another exception is with low-viscosity fluids at high pressures where the slow speed enables slip to equal the theoretical displacement, resulting in no net output flow. To avoid this situation and assure the pump is running at a suitable volumetric efficiency, the pump should always run within its permitted speed range. Figure 17 shows a typical speed versus viscosity curve for a rotary pump.

Since flow is directly proportional to speed, it can be tempting to increase the pump speed above its maximum speed to obtain more flow. However, besides all the aforementioned concerns, one other item must be considered. With any rotary pump, as the cavities rotate, they present a void for the incoming fluid to fill. This void is available for a fixed amount of time, and the fluid in the suction chamber must accelerate to fill this void in the available time. The higher the fluid viscosity, the more energy is required to accelerate the fluid to fill the void. If the fluid cannot fill the void in the time available, a partial void and cavitation will occur.

Pressure The absolute pressure of the fluid at any location in the pump, expressed in lb/in^2 (bar), is the total pressure there and the basis for all other pressure definitions associated with pump operation. Helping to simplify matters, the velocity pressure P_{vel} component of the fluid is usually small enough relative to the total pressure to be neglected.

FIGURE 17 Typical speed reduction as a function of viscosity (In this range, centistokes = SSU/4.6)

In addition, where the fluid velocities (at the same pump locations used to determine the pressure differences) are sufficiently alike, they will cancel each other out. Should this not be so, velocity or dynamic pressure P_{vel} can be computed as

in USCS units
$$P_{vel} = \frac{wV^2}{288g} \quad (6)$$

in SI units
$$P_{vel} = \frac{wV^2}{20,387g}$$

where P_{vel} = dynamic pressure of the fluid being pumped

w = fluid specific weight (mass), lb/ft³ (kg/m³)

V = fluid velocity, ft/s (m/s)

g = acceleration due to gravity, ft/s² (m/s²)

or can alternately be expressed as

in USCS units
$$P_{vel} = 0.000357 \left(\frac{w}{g} \right) \times \left(\frac{Q}{a} \right)^2 \quad (7)$$

in SI units
$$P_{vel} = 13,600 \left(\frac{w}{g} \right) \times \left(\frac{Q}{a} \right)^2$$

where Q = flow, gpm (m³/min)

a = cross-sectional area perpendicular to flow, in² (mm²)

Several pressure terms are of interest. The *outlet* or *discharge pressure* P_o is the total pressure at the outlet of the pump. In pumps with multiple outlets, this pressure is usually defined at the location in the outlet manifold where the pump is mated to the external piping system. Although composed of the sum of system and velocity pressures external to the pump, the outlet pressure is most commonly expressed as the gage pressure at the outlet port. The gage pressure (lb/in² gage or bar) is the difference between the absolute pressure and atmospheric pressure at the point of measurement.

The *inlet* or *suction pressure* P_{in} is the total pressure at the inlet to the pump or, for multiple-inlet pumps, at the manifold location where the pump connects to the external piping system. In common practice, the inlet pressure can be variously expressed as absolute pressure (lb/in² absolute or bar), as positive or negative gage pressure (lb/in² gage or bar), or as vacuum (inches or millimeters of mercury).

The total *differential pressure* P_d is the algebraic difference between the outlet pressure and the inlet pressure, with both expressed in the same units. This differential pressure is used in the determination of power input and in evaluating the slip characteristics of the pump:

$$P_d = P_{out} - P_{in} \quad (8)$$

The *net inlet pressure* $P_{net\ in}$ of a rotary pump is the difference between the inlet pressure expressed in absolute units and the vapor pressure of the fluid expressed in absolute units:

$$P_{net\ in} = P_{in} - P_{vapor} \quad (9)$$

Expressed as head of the pumped liquid, this is the net positive suction head, *NPSH*. The required *NPSH* or *net inlet pressure required* P_{nir} is the minimum net inlet pressure that can exist without the creation of enough vapor in the inlet to interfere with proper operation of the pump. The inlet pressure usually is not the true minimum pressure in the OTI volume. The flow of fluid in its passage through the OTI volume causes a fluid friction pressure loss, which causes the pressure to drop below the inlet pressure at some point in the OTI volume or inlet chamber. This loss increases with fluid velocity and hence with pump speed and fluid viscosity. It is a function of the pump geometry, which determines the fluid path lengths and local velocities where the fluid changes direction in flowing around curves or corners in the pump OTI volume boundary.

The required net inlet pressure is established by the manufacturer for particular speeds, pressures, and fluid characteristics. In practice, the pump user is warned that the net inlet pressure is near or at the required net inlet pressure by noisy and rough operation of the pump caused by the incomplete filling of the CTIO volume with an accompanying reduction in pump flow rate.

The two other pressure ratings used are the maximum allowable working pressure, which is the maximum gage pressure at the outlet port permitted for safe operation. It is usually determined by the stiffness and strength of the pump body and the type of seals used. The maximum differential pressure is the maximum allowable difference between the outlet pressure and the inlet pressure, measured in the same units, and is determined by the capability of the rotating assembly and its fluid seal contact zones to withstand the pressure difference between the OTO and OTI volumes.

Power Most of the pump *input shaft power* HP_{in} (kW_{in}) is the power imparted to the fluid delivered by the pump at given operating conditions and is frequently called *liquid* or *hydraulic power* HP_{hyd} (kW_{hyd}). A common unit used for expressing power ratings is horsepower (kilowatts) and can be computed by the equation:

$$\text{In USCS units} \quad HP_{hyd} = \frac{Q_d \times P_d}{1714} \quad (10)$$

$$\text{In SI units} \quad kW_{hyd} = \frac{Q_d \times P_d}{36}$$

where the constant 1,714 (36) gives the hydraulic power input in *hp* (*kW*) when Q_d is in gpm (m^3/h) and P_d is the differential pressure in lb/in^2 (bar). This is the theoretical power or the required power independent of mechanical friction power losses, and fluid friction power.

The *mechanical friction power losses* HP_{losses} (kW_{losses}) have two components. One is the mechanical friction power required by the elements outside the pumping chamber, such as the bearings and seals, and is usually independent of the fluid being pumped, the pump speed, and the differential pressure. The mechanical friction power inside the pumping chamber depends also on the pump speed and pump differential pressure, but it also depends on the viscosity and lubricity of the fluid.

The *fluid friction power losses*, or *viscous power losses*, are a function of the viscosity of the liquid being handled and on the shear rate in the fluid, which is a function of pump design and pump speed. When handling high-viscosity liquids, the viscous friction power

grows with viscosity, even if speed and pressure remain constant. This power loss depends on a number of design features of the pump and usually will grow proportionally to the viscosity to the n th power, where n usually ranges between 0.3 and 1.0 for most rotary pumps. Increasing any clearances in a pump reduces the shear stress in the liquid in those clearances at any given speed and consequently reduces the torque to overcome the viscous friction.

The *useful output power* HP_{out} is less than HP_{hyd} by an amount $HP_{slip\ loss}$ due to leakage Q_{slip} through the clearances. Thus, *overall efficiency* $E_{overall} = HP_{out} / HP_{in}$, where (for SI units, substitute kW for HP)

$$HP_{in} = HP_{slip\ loss} + HP_{mech\ loss} + HP_{friction\ losses} + HP_{out} \quad (11)$$

Efficiency Rotary pumps are measured by their *volumetric*, *mechanical*, and (as just defined) *overall* efficiencies. This often requires certain trade-offs when selecting a pump for a given set of conditions since a rotary pump does not have a *single best efficiency point* (BEP) the way a centrifugal pump does.

Volumetric efficiency E_{vol} compares actual to theoretical output flows. It is an indication of both a pump's capability to handle a given differential pressure and viscosity and, in the case of older pumps, an indication of possible internal wear. The more flow a pump can deliver under these conditions, the higher its volumetric efficiency will be. The volumetric efficiency of a rotary pump is defined as

$$E_{vol} = \frac{Q_d - Q_s}{Q_d} \quad (12)$$

where Q_d = displacement or geometric flow delivered, in gpm (m^3/hr)

Q_s = slip flow, in gpm (m^3/hr)

The positive displacement nature of rotary pumps makes them suitable for many metering applications. The pump would be a perfect metering device with zero errors if there were no slip. It would be considered a dependable meter if the slip were low or maintained constant over the entire range of operating conditions. A useful ratio in a comparison of different types of rotary pumps for a given metering application is the ratio of minimum flow rate in any of the operating conditions to the maximum flow rate in any of the operating conditions at a given speed. In variable-speed applications, the ratio of minimum volumetric efficiency to maximum volumetric efficiency is substituted. The metering effectiveness is highest as this ratio approaches unity. The difference between this ratio and 1×100 is the percentage of change that can be expected either in the flow rate of the pump or in the total amount of fluid displaced for a given number of revolutions under extremes of operating conditions (such as pressures, temperatures, viscosities, and so on).

Volumetric efficiencies fall in the range of 65 to 98 percent for most rotary pumps. A changing volumetric efficiency over time usually indicates changing system conditions of service or pump wear.

Mechanical efficiency E_{mech} is the ratio of the pump input hydraulic power to input shaft power. It can also be looked at as the comparison of theoretical input power required for the actual power required. The less power a pump requires to produce a given amount of hydraulic work (output), the higher its mechanical efficiency. The total volume of fluid Q_d handled by the pump is larger than Q when slip is present. The amount of slip actually represents wasted power and affects pump efficiency. The difference between shaft power input and hydraulic power input consists of the power lost to mechanical friction and the power lost to fluid friction (a function of the viscosity of the fluid and pump shear stresses on the fluid). The mechanical efficiency of a rotary pump is found by the equation

$$E_{mech} = \left\{ \frac{HP_{hyd}}{HP_{in}} \right\} = \left\{ \frac{HP_{hyd}}{HP_{hyd} + HP_{losses}} \right\} \quad (13)$$

Overall efficiency $E_{overall}$ is the most important efficiency because it alone determines the overall effectiveness of a pump for an application. That is, knowing only the volumetric or mechanical efficiencies can result in misleading conclusions. Only with a satisfactory

overall efficiency one can be reasonably assured of overall satisfactory performance. Overall efficiency is defined in terms of E_{mech} and E_{vol} as follows:

$$\text{in USCS units} \quad E_{overall} = \left\{ \frac{Q_d - Q_{slip}}{Q_d} \right\} \times \left\{ \frac{HP_{hyd}}{HP_{hyd} + HP_{losses}} \right\} \quad (14)$$

$$\begin{aligned} \text{in SI units} \quad &= \left\{ \frac{Q_c}{Q_d} \right\} \times \left\{ \frac{kW_{hyd}}{kW_{in}} \right\} \\ &= E_{vol} \times E_{mech} \end{aligned}$$

Another way of looking at overall efficiency is

$$E_{overall} = \left\{ \frac{Q_{actual}}{Q_{theoretical}} \right\} \times \left\{ \frac{HP_{theoretical}}{HP_{actual}} \right\} \quad (15)$$

Pump Performance Figures 18, 19, and 20 show the change in displacement capacity Q_d , flow rate or capacity Q_c , and slip Q_s as the differential pressure across the pump P_d , the viscosity ν , and the pump speed N are varied. Several assumptions are made in these graphs. It is assumed that inlet conditions are satisfactory and that there is no inlet effect on the pump capacity over the charted range. It is assumed that the fluid is Newtonian and the liquid is incompressible. In Figures 18 and 19, it is assumed that viscosity is constant and relatively low, and that the speed is within the normal range of the pump. In Figure 20, it is assumed that both pressure and speed are within the normal ratings of the pump.

The graph in Figure 18 is plotted with the flow rate, slip, and displacement flow rate on a linear scale as the ordinate (Y-axis) and pressure on a linear scale as the abscissa (X-axis). A further assumption is that the clearances and viscosity are such that the slip increases proportionately with pressure. The solid lines are the ideal characteristics when secondary effects are neglected. It may be noted that at zero pressure, slip Q_s is zero and Q_c equals Q_d . As the pressure increases, Q_s increases until it equals Q_d at pressure B. If the pressure imposed on the pump were to increase past this point, Q_s would exceed Q_d and the flow through the pump would be from outlet to inlet, causing a negative Q_c .

FIGURE 18 Variation of Q_d , Q_c , and Q_s with P_d , N and ν constant

Although rotary pumps do not operate in this end of the pressure range, the condition of pressure B can be reached when a valve is closed, blocking the outlet of the pump. Pressure B , then, represents dead-ended pressure developed by a rotary pump when its outlet line is blocked. Should Q_d be numerically equal to 100 in whichever units are used, then the plot of Q_c is numerically equal at each point to the volumetric efficiency E_{vol} of the pump and Q_c becomes zero at pressure B .

Pressure B data is usually not available from pump manufacturers since these values are usually far beyond the normal safe pressure rating of the pump. However, they can be estimated by extrapolating the data given. Cautions should be observed, however. A flexible member can quickly reach a pressure at which flexible member deflection becomes excessive, and the pressure at which Q_c equals zero is very quickly reached. This is illustrated in Figure 18 by the dashed line breaking away from the solid Q_c line and intersecting the abscissa at pressure point A . This characteristic of flexible member pumps provides a self-limited maximum pressure should the pump be dead-ended. In rigid rotor pumps, as the pressure increases beyond the normal operating range, deflections of the shafts and rotors bring the rotors into heavy bearing contact with the body chamber walls, reducing the dimensions of the slip clearance path. The dashed line leaving the Q_c and Q_s curves and intersecting the abscissa and Q_d line at pressure point C illustrates this. Consequently, the zero flow pressure, which is ideally at point B , may be considerably different from this extrapolated value, and it should be measured if it is important to the application.

Under the same assumptions given for Figure 18, Figure 19 shows the relative independence of the slip with speed when differential pressure is constant. Here the chart of Q intersects the abscissa at the point where the speed is low enough for the displacement flow rate to be equal to the slip at the pressure of operation. The speed at which Q_d equals $2 \times Q_s$ is the speed at which Q_s equals Q_c and the volumetric efficiency E_{vol} becomes 50 percent.

As the speed increases, the pumping action of the shear stress in the clearances tends to reduce the slip below the ideal line. However, for most rotary pumps, the detrimental effects of increasing the speed above the normal operating range is usually caused by inlet losses in the pump. This effect is cavitation and is illustrated by the dashed line, for which the net inlet pressure (N. I. P.) or $NPSH$ is less than that required.

Figure 20 shows the effect of viscosity on the slip and flow rate in a rotary pump. The graphs are on a log-log scale. In this chart, it is assumed that the pressure, speed, and viscosity combine to keep the flow through clearances of the pump in the laminar or "viscous" flow region.

FIGURE 19 Variations of Q_d , Q_c , and Q_s with N , P_d , and v constant

FIGURE 20 Variations of Q_d , Q_c , and Q_s with ν , N and P_d constant

As viscosity increases, slip Q_s becomes very small and the flow rate of the pump Q_c approaches the displacement flow rate Q_d . As the viscosity decreases, the slip very rapidly approaches the displacement flow rate and the flow rate of the pump drops rapidly to zero or to a negative quantity. For any given pump with speed N and differential pressure P_d , there is a viscosity below which the slip flow, through clearances of the pump, will change to a turbulent flow. It is unlikely that this change will occur simultaneously through all slip paths. However, once it begins to occur, the slip will increase much more rapidly with further reductions in viscosity because of the turbulent flow relationship of the slip, pressure, and viscosity expressed in Equation 16:

$$Q_s = \frac{KP_d^{1/2}}{\nu^{1/x}} \quad (16)$$

where x usually is in the range of four to 10, and K is a constant.

Volumetric efficiency E_{vol} drops very rapidly with the viscosity if the viscosity is lower than that required for 50 percent volumetric efficiency (represented by the crossover point of the slip and capacity curves). This crossover point occurs for most rotary pumps operating at rated differential pressure P_d for viscosities between 0.1 and 10 centipoise. For the majority of commercially available models, this point usually falls in the viscosity range of 0.3 to 3.0 centipoise at the maximum rated differential pressure.

The effect of inlet pressure on the capacity can be seen clearly if all secondary effects are eliminated. This assumes the pump is operating within its normal pressure limits and speed range and that viscosity is high enough to reduce the slip to a negligible value. A graph of the capacity as a function of inlet pressure is shown in Figure 21 with these assumptions.

There is no change in capacity or flow rate as inlet pressure is lowered until the pressure reaches pressure A on the graph. If the inlet pressure were lowered further, the flow rate would drop as shown. The cause of this drop is complex in detail but simple in concept. The liquid flow from the inlet port through the inlet chamber of the pump causes a pressure drop, which causes a minimum pressure point somewhere in the inlet chamber. When the pressure in the liquid at this minimum pressure point approaches the vapor pressure of the liquid, vapor begins to form there. When the amount and time persistence of this vapor cause the vapor to be swept into the CTIO volume of the pump, the amount

FIGURE 21 Variations of Q_c and P_{in} with other operating conditions constant

of liquid in this volume is reduced, leaving a deficiency of liquid volume. For example, if half the fluid volume swept from the inlet chamber is vapor, then only half the normal-capacity liquid volume is available at the outlet chamber, and the flow rate is reduced accordingly.

An increase in speed would mean an increase in flow rate, all other things being equal. This would increase the pressure drop between the inlet port and the inlet chamber and correspondingly increase the absolute inlet pressure (which is measured at the inlet port) at which the flow rate would begin to drop (pressure A). Correspondingly, if the speed and flow rate were constant and the viscosity increased, the pressure drop between the inlet port and the minimum pressure point in the inlet chamber would increase with viscosity. This also would cause pressure A to move to higher inlet absolute pressures. Operation with absolute inlet pressures below pressure A for any given speed and viscosity is usually unsatisfactory both because of the drop in capacity (and hence in volumetric efficiency) and because of the noisy and rough operation caused by the formation and collapse of the vapor.

For lower viscosity liquids where the collapse of the vapor bubbles may be quite rapid, cavitation may cause a significant amount of damage to the body or rotor surfaces. It is important to understand that cavitation damage may occur even though the absolute inlet pressure is above pressure A. Locations may be found in the inlet chamber, particularly where the flow direction changes rapidly, as around sharp corners, where vapor formation in the form of very fine bubbles, and hence cavitation, may occur. However, these vapor cavities may be swept into higher pressure regions of the inlet chamber and collapse near body or rotor surfaces to cause cavitation damage, although the capacity of the pump is not affected. For any given viscosity then, there is an upper limit to the speed at which the pump can be operated.

The inlet pressure may be allowed to drop slightly below pressure A without a significant deterioration in pump performance. However, there is a point at which the pressure becomes too low for satisfactory pump operation. This pressure determines the required net inlet pressure P_{nipr} or $NPSHR$ for the particular pump and the particular set of operation conditions. For any given set of operating conditions, satisfying the required net inlet pressure or $NPSHR$ is a main limitation on the pump operating speed.

The other main limit on the pump operating speed is the pump outlet pressure. In every application, some fluid frictional losses occur in the outlet system of the pump. Even if the pump outlet is opened to the atmosphere, a pressure drop exists between some maximum pressure point in the pump outlet chamber and the pump outlet itself. However, by far, the

as Q_3 , is equal to the displacement flow rate Q_d as speed is increased until a speed is reached at which the available net inlet pressure of the pump drops to the required net inlet pressure of the pump. If the speed is increased beyond this point, the capacity of the pump would drop rapidly as an ever-increasing part of the pump fluid becomes vapor instead of liquid.

The upper limit of speed for satisfactory operation of the pump is shown as N_1 , N_2 , and N_3 for the three conditions described. The locations of N_1 , N_2 , and N_3 on the speed axis are independent of each other because they depend primarily on the operating conditions of the pump, the system in which it operates, and on the conditions of the pumped fluid. For example, a negative head in the outlet system could cause N_3 to move to a higher value than N_2 , and N_2 to move to a higher value than N_1 . Operation with a liquid with lower viscosity (but still sufficient to reduce the slip to zero) could cause N_3 to be higher than N_1 .

In most applications, one of the two limits described determines the maximum permitted speed of pump operation. However, if neither of these conditions limits the speed and the speed is continuously increased, a speed will be reached at which the peripheral velocity of the rotors will exceed the cavitation velocity of the liquid. A further increase in speed beyond this point would be limited by the cavitation occurring at the rotor outer radial surfaces.

SPECIFICATIONS, INDUSTRIES, AND APPLICATIONS

In addition to the many application-oriented classifications for vane, gear, or lobe pumps, many technical classifications are also issued by various industrial, governmental, or even military organizations. It is also important for both the manufacturer and the user to know of any voluntary or regulatory specifications governing the construction and materials of the pumps destined for use in a specific industry and application.

Many industry-based specifications, such as the International Association of Milk, Food, and Environmental Sanitarians, the United States Public Health Service, and the Dairy Industry Committee, have jointly issued specifications called "The 3-A Sanitary Standards for Pumps for Milk and Milk Products." These standards govern the materials of construction of the pump, the surface finish and shape details of the contact surfaces, the finish and shape of external surfaces, the method of mounting, and restrictions on gaskets, seals, and other pump auxiliary features. Pumps constructed to meet 3-A Sanitary Standards are called *sanitary* pumps and carry a 3-A seal of approval mounted on the pump body. Similar specifications have been developed by the International Association of Milk, Food, and Environmental Sanitarians, the United States Public Health Service, the United States Department of Agriculture, the American Poultry Industries, and the Dairy and Food Industries Supply Association to cover design features used in the handling of cracked eggs.

Standards for pumps used in various processes in the petroleum industry are concerned with the materials and design features that are intended to prevent catastrophic failures when explosive, flammable, or toxic fluids are being handled. Others generated by governmental agencies and professional societies, such as the American Society of Mechanical Engineers and the American Petroleum Institute Standard 676, establish manufacturing procedures and design limitations on pumps for refineries, nuclear power stations, and so on. In these cases, the terms *sanitary*, *aseptic*, *explosion proof*, *API pump* or *N stamp* are not merely generic terms and cannot be casually applied. They must instead be carefully applied and used only when the manufacturer warrants that the pumps actually meet these specifications. In addition, as an unavoidable consequence, the cost of manufacturing pumps to meet any of these standards makes them more expensive than pumps built for general service applications.

Rotary pumps are used for both metering and transfer applications; so, most vane, gear, and lobe pumps are found in these services. Metering pumps tend to be smaller and operate with varying flow rates. Transfer pumps typically have a fixed speed, although variable speed units are becoming more common as the cost for this equipment falls.

In general, the three most basic applications for these pumps are as follows:

1. **Liquid handling** In this class, well over 2,000 fluids are pumped and performance is judged on the pump's capability to handle the specific liquids, and the hydraulic power generated by the pump is a secondary consideration.

- 2. Hydraulic fluid power** In this class, the hydraulic power generated by the pump is used to actuate valves, pistons, cylinders, rotary actuators, and similar devices. Pumps in this class are usually vane, gear, piston, or screw types and are designed for pressures up to 9,000 lb/in² (620 bar) on selected hydraulic power fluids.
- 3. Commercial and retail** In this class are the pumps designed for a single specific use, application, or even fluid. Pumps in this miscellaneous class include everything from miniature pumps for home aquariums to well water pumps for agricultural use to fuel injection pumps for automobiles.

Among these three application areas, the most common is liquid handling tasks, and they make up the largest percentage of uses for rotary vane, gear, and lobe pumps.

Markets and Applications The markets and applications served by vane, gear, and lobe pumps are among the broadest of all rotary pumps. Although it would not be possible to list every application served by these pumps, a broad sampling of the more common ones is shown in Table 3.

SUMMARY

In this section, we have discussed vane, gear, and lobe pumps in a general sense and covered many of the technical attributes that give them their unique characteristics. From an applications standpoint, the advantages these pumps have over other types can be summarized in Table 4.

TABLE 3 Markets and applications

TABLE 4 The basic features and applications benefits of the main rotary pumps*

| Vane, Gear and Lobe Pumps | |
|---|---|
| Feature | Benefit |
| Flow largely independent of pressure | Predictable pump performance over varying system conditions |
| Wide hydraulic coverage- Flows to 10,000 GPM, differential pressures to 5,000 PSI | Few applications a rotary pump can't handle |
| Efficiently handles high viscosity fluids- over 100,000 SSU in some cases | Lower operating cost as efficiencies actually increase with viscosity |
| Smooth, pulse-free flow | Less system cost no need for vibration isolators or vibration dampeners |
| Self priming and will not vapor lock | Less system complexity - no need to prime or re-prime |
| Non-shearing pump action | Will not degrade shear sensitive polymers and petrochemicals |

*10,000 gpm = 2,300 m³/h; 5000 psi = 345 bar; 100,000 SSU =21,600 centistokes.

Many other types of rotary pumps were included in this discussion. The three types discussed here, and the numerous design variations of each type, constitute the bulk of rotary positive displacement pumps in use today.

JET PUMPS

SECTION 4.1

JET PUMP THEORY

RICHARD G. CUNNINGHAM

INTRODUCTION

The jet pump transfers energy from a liquid or gas primary fluid to a secondary fluid. The latter may be a liquid, a gas, a two-phase gas-in-liquid mixture, or solid particles transported in a gas or a liquid. Examples of all these combinations have been reported in the technical literature. Reference 1, the major bibliography in this field, contains over 400 abstracts. Although the terms “ejector” and “eductor” are also applied, the term “jet pump” will be used here. The jet pump offers significant advantages over mechanical pumps: no moving parts for improved reliability, adaptability to installation in remote or hazardous environments, simplicity, and low cost. The primary drawback is efficiency: both frictional losses and unavoidable mixing losses are incurred. Nevertheless, careful design can produce pumps with efficiencies on the order of 30–40%. The jet pump in Figure 1 is typical of liquid-jet pumps and low Mach-number gas-jet/gas pumps. Compressible-flow pumps, for example, steam-jet ejectors, employ converging-diverging nozzles for full expansion of the jet.

NOMENCLATURE

A = area, ft² (m²)

A_w = throat wall area, ft² (m²)

C = velocity of sound, ft/sec (m/s)

CR = cavitation resistance

D = diameter, ft (m)

- E = energy rate, ft lb/sec (joule/s)
 K = friction loss coefficient
 $^{\circ}\text{K}$ = absolute temperature, Kelvin
 LJL = liquid-jet liquid pump
 LJG = liquid-jet gas compressor
 LJGL = liquid-jet gas and liquid pump
 M = liquid/liquid flow ratio, Q_2/Q_1
 MN = Mach number
 N = pressure ratio, LJL jet pump
 NPSH = net positive suction head
 P, P = pressure: static, total psia (kPa abs.)
 P_v = vapor pressure, psia (kPa abs.)
 Q = volumetric rate, ft^3/sec (m^3/s)
 \mathbf{R} = gas constant, ft lbs/slug $^{\circ}\text{R}$ (joules/kg $^{\circ}\text{K}$)
 $^{\circ}\text{R}$ = absolute temperature, Rankine
 S = density ratio, ρ_2/ρ_1
 T = temperature $^{\circ}\text{R}$ ($^{\circ}\text{K}$)
 V = velocity, ft/sec (m/sec)
 W = work rate, ft lbs/sec (joules/s)
 Z = jet dynamic pressure, psi (kPa)
 a = diffuser area ratio, A_i/A_d
 b = jet pump area ratio, A_n/A_i
 $c = A_{2G0}/A_n = (A_i - A_n)/A_n = (1 - b)/b$
 m = mass flow rate, slugs/s (kg/s)
 s = seconds
 psi = pounds per square inch
 psia = pounds per square inch, absolute
 r_v = gas/liquid vol. flow rate ratio Q_G/Q_2
 r_{v0} = gas/liquid vol. flow rate ratio at 0: Q_{G0}/Q_2
 r_m = gas/liquid mass flow-rate ratio
 sp = nozzle-to-throat spacing, ft(m)
 sp/D_{th} = spacing, throat diameters
 η = efficiency
 γ = gas density ratio at s , ρ_{Gs}/ρ_1
 $\gamma\phi_s = m_{Gs}/m_1$
 ρ = density, slugs/ ft^3 (kg/m^3)
 τ = shear stress, psi (kPa)
 ϕ = gas flow ratio Q_G/Q_1
 ϕ_s = gas flow ratio Q_{Gs}/Q_1 at s

Subscripts

- 1 = liquid primary flow
 2 = liquid secondary flow

- G = gas secondary flow
 $2G$ = bubbly secondary flow
 $2G_0$ = bubbly sec. flow at 0
 mep = maximum efficiency point
 op = operating point
 L = limit for cavitating flow
 3 = combined fluids 1, 2, and G
 i, s, n = locations (see Fig. 1)
 $0, t, d$ = locations (see Fig. 1)
 $c0$ = flow-ratio cut off
 f = friction loss
 n = nozzle
 en = throat entry
 th = mixing throat
 di = diffuser
 td = throat and diffuser

Subscript Examples

- Q_2 = secondary liquid vol. flow rate
 Q_{G0} = secondary gas flow rate, at 0
 Q_{2G0} = flow rate of bubbly mixture of gas in the secondary liquid, at 0

NOTE: The convention for pressure and stress in this section is to use psi (and psia) for pounds per square inch (and pounds per square inch absolute) instead of the conventional lb/in² used throughout the rest of the handbook.

FIGURE 1 Liquid-jet gas and liquid pump and nomenclature

LIQUID-JET PUMP THEORY FOR THREE SECONDARY-FLOW TYPES

The liquid-jet pump model is based on conservation equations for energy, momentum, and mass. Real-fluid losses are accounted for by friction-loss coefficients (K). The primary or motive fluid is a liquid of density ρ_1 . In the following derivation, the secondary/pumped fluid

can be a second liquid of density ρ_1 or ρ_2 , or a gas-in-liquid bubbly mixture, or a gas. These three jet pump flow regimes are referred to as liquid-jet liquid (LJL), liquid-jet gas liquid (LJGL), and liquid-jet gas (LJG). Equations (1), (3), (5), and (7) below apply to all three.

Assumptions:

- a. The primary and secondary streams enter the mixing throat with uniform velocity distributions, and the mixed flows leave the throat and diffuser with a uniform velocity profile.
- b. The gas phase—if present—undergoes isothermal compression in the throat and diffuser.
- c. All two-phase flows at the throat entry and exit consist of homogeneous bubble mixtures of a gas in a continuous liquid.
- d. Heat transfer from the gas to the liquid is negligible—the liquid temperature remains constant.
- e. Change in solubility of the gas in the liquid from pressure P_s to P_d is negligible.
- f. Vapor evolution from and condensation to the liquid are negligibly small.

NOZZLE EQUATION With reference to Figure 1

$$P_i + \rho_1 \frac{V_i^2}{2} = P_o + \rho_1 \frac{V_n^2}{2} + K_n \rho_1 \frac{V_n^2}{2} \quad (1)$$

For

$$P_i = \bar{P}_i$$

the nozzle equation is

$$P_i - P_o = Z(1 + K_n)$$

THROAT-ENTRY EQUATION The two-phase secondary flow is described by

$$\frac{dP}{\rho} = VdV + d\left(K_{en} \frac{V^2}{2}\right) = 0 \quad (2)$$

Density of the secondary fluid as a function of static pressure and flow ratios M and ϕ is

$$\rho_{2G} = \frac{m_2 + m_G}{Q_2 + Q_G} = \frac{m_1 \left[\frac{m_2}{m_1} + \frac{m_G}{m_1} \right]}{Q_1(M + \phi)} = \rho_1 \left[\frac{SM + \gamma\phi_s}{m + \phi} \right]$$

Integration of Eq. (2) using this density relation and continuity results in the throat-entry equation:

$$M(P_s - P_o) + P_s \phi_s \ln \frac{P_s}{P_o} = Z \frac{SM + \gamma\phi_s}{c^2} (1 + K_{en})(M + \phi_o)^2 \quad (3)$$

MIXING THROAT MOMENTUM EQUATION Equating control volume forces and fluid momentum changes:

$$(P_0 - P_t)A_{th} - \tau A_w = (m_1 + m_2 + m_G) V_{3t} m_1 V_n - (m_2 + m_G) V_{2Go} \quad (4)$$

where

$$\frac{\tau A_w}{A_{th}} = \frac{K_{th} \rho_{3t} V_{3t}^2}{2}$$

Substituting the density and continuity relations in Eq. (4) and dividing A_{th} produces a quadratic equation in P_t . The throat momentum equation becomes

$$\begin{aligned} P_t^2 - Z \left[2b - b^2(2 + K_{th})(1 + SM + \gamma\phi_s)(1 + M) \right. \\ \left. + 2(SM + \gamma\phi_s)(M + \phi_0) \frac{b^2}{(1 - b)} + \frac{P_0}{Z} \right] P_t \\ \left. + Z[b^2(2 + K_{th})(1 + SM + \gamma\phi_s)P_s\phi_s] = 0 \right. \end{aligned} \quad (5)$$

DIFFUSER EQUATION The mixed primary and secondary fluids flow from t to d :

The t - d flow is described by Eq. (6):

$$\int_t^d \frac{dP}{\rho} + \int_t^d V dV + \int_t^d \frac{\Delta P_f}{\rho_{3t}} = 0 \quad (6)$$

Integrating Eq. (6) and substituting the density and continuity relations, the diffuser equation becomes

$$\begin{aligned} (P_d - P_t) + \frac{P_s \phi_s}{1 + M} \ln \frac{P_d}{P_t} = Z b^2 \left[\frac{1 + SM + \gamma\phi_s}{1 + M} \right] \\ \times [(1 + M + \phi_t)^2 - \alpha^2(1 + M + \phi_d)^2 - K_{di}(1 + M + \phi_t)(1 + M)] \end{aligned} \quad (7)$$

LIQUID-JET PUMP EQUATIONS The liquid jet pump is described in terms of the four flow processes by Equations (1), (3), (5), and (7). The term $\gamma\phi_s = \rho_{Gs} Q_{Gs}/\rho_l Q_l$. For isothermal flow, $\gamma\phi_s = 144 P_s \phi_s / \mathbf{R} T_s \rho_1$. For air, with $\mathbf{R} = 1716$ ft lb/slug $^{\circ}\mathbf{R}$, and water, $\rho_1 = 1.94$ slugs/ft³ and $\gamma\phi_s = .0432 P_s \phi_s / T_s$. In SI, $\mathbf{R} = 286.92$ mN/kg $^{\circ}\mathbf{K}$, $\rho_1 = 1000$ kg/m³, and $\gamma\phi_s = .00348 P_s \phi_s / T_s$, with P_s in kN/m², and T_s in $^{\circ}\mathbf{K}$. The \mathbf{R} and/or ρ_1 values must of course be replaced for fluids other than water and air.

In the LJGL pump, the secondary flow is a bubbly mixture of a gas in a liquid. Compressible flow phenomena must be considered because the velocity of sound is quite low in bubbly fluids. For example, the velocity of sound in a 50/50 uniform mixture of air in water is about 70 ft/s (21.3 m/s), far below sonic velocities in air (1100 ft/s or 335 m/s) or water (5000 ft/s or 1524 m/s).

The Mach number of a bubbly secondary flow at the throat entrance is (see Reference 5):

$$\text{MN}_{2G0} = \frac{V_{2G0}}{C_{2G0}} = \frac{\phi_0}{c} \sqrt{\frac{2Z}{P_s \phi_s}} (SM + \gamma \phi_s) \quad (8)$$

When this Mach number is 1.0, the LJGL pump has reached limiting flow; that is, a reduction in back pressure P_d no longer causes an increase in the bubbly secondary-flow rate.

Pump Efficiencies The LJGL pump produces two useful work results:

- Static-pressure increase of the liquid component of the secondary flow stream.
- If a gas is entrained in this liquid stream, isothermal compression of the gas component.

With W as the work rate, ft-lb/s, (power) $W_L = Q_2(P_d - P_s)$ is the work rate on the liquid component, and $W_G = \rho_{Gs} Q_{Gs} R T \ln(P_d - P_s)$ is the work rate on the gas component. The energy rate input is $E_{in} = Q_1(P_i - P_s)$. The LJGL pump mechanical efficiency is the total work rate divided by the energy rate in

$$\eta = \frac{M(P_d - P_s) + P_s \phi_s \ln \frac{P_d}{P_s}}{P_i - P_d} = \eta_L + \eta_G \quad (9)$$

The Jet Loss Jet pumps in practical applications have nozzle-to-throat spacings sp/Dth of one or more mixing-throat diameters. The power jet traverses from a static pressure at or near P_s down to P_o , with no useful work recognized in the one-dimensional theory. Thus a “jet loss” occurs, which is in addition to the frictional and mixing losses (see Reference 9).

In the LJL and LJGL (but not the LJG) pumps, throat-inlet pressure drops—and hence jet losses—are significant (Ref. 6).

Pump Efficiency, Incorporating Jet Loss In Eq. (9), $(P_i - P_d)$ is expanded: $(P_i - P_d) = (P_i - P_s) - (P_d - P_s)$, and $(P_i - P_s) = (P_i - P_o) - (P_s - P_o) = Z(1 + K_n) - j(P_s - P_o)$, where $j = 1$ for a fully inserted nozzle, *no jet loss*; and $j = 0$ for the usual case of retracted nozzle, which produces *full jet loss*. Eq. 9 now becomes

$$\eta = \frac{M(P_d - P_s) + P_s \phi_s \ln \frac{P_d}{P_s}}{Z(1 + K_n) - j(P_s - P_o) - (P_d - P_s)} = \eta_L + \eta_G \quad (10)$$

Eq. (10) is recommended for predicting liquid-jet pump efficiencies as follows: Use $j = 0$ for pumps with normally-retracted nozzles (full jet loss); use $j = 1$ for no-jet-loss pumps (thin-walled nozzle tip fully inserted so $sp = 0$). The pressure in Eq. (10) should be calculated from the one-dimensional theory using Eqs (1), (3), (5), and (7). (See below for the LJL jet pump.)

Computer Programs for LJGL and LJG Models Solutions for the compressible flow cases are generated using computer spreadsheet or Fortran programs. Values for Z , b , P_s , T_s , R , ρ_1 , S and the four K coefficients are fixed/assumed for each pump and operating conditions. Eqs. (3), (5), and (7) are then solved for each step increase in flow-ratio M , with ϕ_s held constant. Alternatively, M may be held constant and the equations solved for step increase in ϕ_s . Eqs. (3), (5), and (7) are interdependent: solution of Eq. (5) requires P_o values from Eq. (3) and solution of Eq. (7) requires P_i values from Eq. (5). The program outputs at each flow-ratio step are static pressure P_o , P_i , P_d , and the three pump efficiencies defined by Eq. 10.

LJGL FLOW CUT-OFF Compressible-flow choking of the secondary stream at the throat entrance will occur at $\text{MN}_o = 1$. The flow ratio at which this will occur can be predicted from critical-flow theory. For further details, see Reference 5.

Performance of the gas compressor (LJG) can be calculated from Eqs. (1), (3), (5), and (7) by setting $M = 0$. Although simplified, the equations are still coupled as in the LJGL case. The one-dimensional theory predicts actual performance quite well (see References 6 and 7) provided the mixing is completed within the length of the mixing throat. Theory-experiment agreement fails and the gas compressor efficiency declines—mixing is allowed to extend into the diffuser.

THE LIQUID-JET LIQUID (LJL) PUMP

Equations for the LJL pump are much simpler than the corresponding LJGL and LJG equations because of the elimination of all ϕ terms. In this case, Eqs. (1), (3), (5), and (7) reduce to the following set:

$$\text{Nozzle} \quad P_i - P_o = Z(1 + K_n) \quad (1)$$

$$\text{Throat Entry} \quad P_s - P_o = ZS(1 + K_{en})M^2/c^2 \quad (11)$$

$$\text{Throat} \quad P_t - P_o = Z[2b + 2SM^2b^2/(1 - b) - b^2(2 + K_{th})(1 + SM)(1 + M)] \quad (12)$$

$$\text{Diffuser} \quad P_d - P_t = Z_b^2(1 + SM)(1 + M)(1 - K_{di} - a^2) \quad (13)$$

Pump efficiency η is defined as the ratio of useful work rate on the secondary fluid Q_2 to the energy extracted from the primary liquid:

$$\eta = Q_2(P_d - P_s)/Q_1(P_i - P_d) = MN \quad (14)$$

Two other definitions of efficiency are found in the literature, as follows:

$$\eta' = Q_2(P_d - P_s)/Q_1(P_i - P_s) = \eta/N + 1$$

$$\eta'' = (M + 1)(P_d - P_s)/(P_i - P_s)$$

These two other definitions assume that the primary/power stream pressure falls to P_s , not P_d , as shown in Figure 2. Efficiency conversions are possible only if all three pressures and two flow rates involved are given. Comparisons of efficiencies reported in the literature should be made with caution.

Combining Eqs. 1, 11–14, the theoretical pressure characteristic N for the LJL pump is

$$N = \frac{2b + \frac{2SM^2b^2}{1-b} - b^2(1 + K_{td} + a^2)(1 + M)(1 + SM) - \left(\frac{SM^2}{c^2}\right)(1 + K_{en})}{1 + K_n - 2b - \frac{2SM^2b^2}{1-b} + b^2(1 + K_{td} + a^2)(1 + M)(1 + SM) + (1 - j)\left(\frac{SM^2}{c^2}\right)(1 + K_{en})} \quad (15)$$

FIGURE 2 LJL jet pump and installation

where $K_{td} = K_{th} + K_{di}$. The term $j = 0$ for the normal (jet loss) case, and $J = 1$ for no jet loss. Jet pumps normally are designed with a finite nozzle-throat spacing, typically $sp/D_{th} = 1$; jet loss is experienced, and thus $j = 0$ for this (usual) case. Eq. (15) becomes

$$N = \frac{2b + \frac{2SM^2b^2}{1-b} - b^2(1 + K_{td} + a^2)(1 + M)(1 + SM) - \left(\frac{SM^2}{c^2}\right)(1 + K_{en})}{1 + K_n - \text{numerator}} \quad (16)$$

In terms of pressure,

$$N = (P_d - P_s)/(P_i - P_d)$$

Two simplifications of Eq. (16) are often appropriate: 1) The area ratio term $a^2 = 0$ for the usual 5°-8° included-angle diffuser ($a = A_t/A_d$ is small). 2) The density ratio $S = 1$ for similar primary and secondary liquids, for example, a water primary jet pumping water as the secondary fluid. With these simplifications, Eq. (16) for the normal (jet loss) case becomes

$$N = \frac{2b + \frac{2SM^2b^2}{1-b} - b^2(1 + K_{td})(1 + M)^2 - \left(\frac{M^2}{c^2}\right)(1 + K_{en})}{1 + K_n - \text{numerator}} \quad (17)$$

And pump efficiency is

$$\eta = \eta_L = MN \quad (18)$$

For the L₂JL jet pump, note also that

$$(P_d - P_s)/(P_i - P_s) = N/(N + 1) \quad (19)$$

Computer Programs for L₂JL Models It is convenient to use Eqs. (17) and (18) in spreadsheet form to generate tables of “ $N(b, M, K_n, K_{td}, K_{en})$,” that is, the L₂JL jet pump pressure characteristic N as a function of the bracketed variables. Typically the K s and the area ratio b are held constant and a table is generated using step increases in M to show resultant N values. Table 1 shows $N(M)$ for $b = .25$; and $K_n = .05$, $K_{td} = .2$, and $K_{en} = 0$. The performance of this pump is shown in Figure 3 as $N(M)$ and $\eta(M)$.

TABLE 1 Performance versus M , for $b = .25$, $K_n = .05$, $K_{td} = .2$, $K_{en} = 0$

FIGURE 3 $K_n = .05, K_{id} = .20, K_{en} = 0$

It has been shown (see References 2, 3, 4) that one-dimensional analyses successfully predict actual LjL pump performance. But theory-experiment agreement obtains only if the test-pump flow conforms with the model assumptions. Two conditions that will cause departure of measured N and η data from the theoretical curves are

- Cavitation, which occurs in the mixing throat
- Extension of the throat mixing process out into the diffuser

Operating Flow Ratio M_{op} In Figure 3, the flow ratio M_{op} is indicated on the left slope of the “parabolic” efficiency curve, which peaks at $M = M_{mep}$. The recommended location of the design operating point is to set $M_{op} = \frac{2}{3} M_{mep}$. Higher operating M ratios would provide slightly higher efficiencies, but at a greater risk of cavitation. (Cavitation as part of the design process is included in the following examples given.) Finding M_{mep} can be readily accomplished from Table 1 type data using spreadsheet successive approximations. Alternatively, Eqs. (17)–(18) can be differentiated and set equal to zero to find the peak efficiency M_{mep} value.

Cavitation LjL pumps may encounter cavitation, which occurs in the mixing throat. With reference to Figure 3, the LjL pump normally responds to a reduction in back pressure P_d (Q_1 and P_s constant) by producing a larger Q_2 secondary flow, and hence a larger M . Measured pressure ratios (N) and efficiencies (η) track along these theory-based characteristic curves as shown in Figure 3. But after the throat-inlet pressure (P_c) is reduced to the vapor pressure (P_v) of the secondary liquid, any further drop in the back pressure has no effect on the flow ratio, which stabilizes at $M = M_L$, the *cavitation-limited flow ratio*. Note the vertical dashed line in Figure 3: measured N and η values fall on this vertical line, under M_L operating conditions. In this manner, cavitating-pump performance departs radically from predicted/normal behavior.

Published studies (see References 1 and 8) have shown that NPSH-type correlations adequately explain and predict cavitation-limited flow phenomena. **Comparing the predicted M_L with the intended M_{op} is an essential step in designing a jet pump**

installation. If $M_{op} < M_L$, the L_JL pump can be expected to perform “on design,” that is, to follow the Eq. (17) $N(M)$ relation, with no cavitation. M_L can be predicted from the operating conditions as follows (see Reference 8):

$$M_L = c \sqrt{\frac{P_s - P_v}{\sigma Z}} \quad (20)$$

where σ is a cavitation coefficient.

Experiments, primarily with water and lubricating oils, have shown a σ range of 0.8–1.4 (see Reference 1). One investigator (see Reference 10) found that improving the nozzle exterior profile and related throat-inlet internal profile reduced the measured σ from 1.4 to 1.0, indicating a significant improvement in cavitation resistance. For design use, a conservative value of $\sigma = 1.35$ is recommended (see Reference 8).

Area Ratio b The nozzle-to-throat area ratio b is the only geometric parameter in these liquid-jet pump models, and including the L_JL case, Eq. (17). Area ratio b is all-important, affecting pump efficiency, flow capacity, cavitation, and pressure characteristic $N(M)$. Comparisons of b -value series of pumps (see References 1–4) show that peak efficiency is highest for $b = .2$ to $.3$. This optimum occurs because efficiency of the jet pump reflects the two unavoidable losses: friction and the mixing loss. The latter (a maximum at zero M) decreases with rising M , whereas frictional losses increase with M . The sum of these losses is a minimum for pumps in the $b = .2 - .3$ range, each operating at or near the respective M_{mep} (see Reference 9). As indicated in the numerical Examples 1 and 2 further on, it is recommended that jet pump designs start—in the absence of other restraints—with $b = .25$. This initial area ratio can then later be adjusted, for example, to handle a cavitation problem. In specific cases the jet pump placement, or a desired flow ratio, may determine N or M , and hence b . Example 3 illustrates the situation.

Friction-Loss Coefficients Solutions of Eqs. (11)–(18) require use of appropriate K loss coefficients. The following sources are suggested:

1. Adopt published results from jet pump studies that have included measurements of K values (see References 3, 10, 11).
2. Use published loss coefficients for the (four) components of the L_JL pump; that is, converging nozzle, tube entry, short tube, and diffuser.
3. Measure K s directly by running flow test of jet pumps or component parts. Full evaluation of the four K s requires measurement of two flow rates and five static pressures, P_i , P_s , P_o , P_t , and P_d . Most studies, however, have omitted P_o and P_t pressure taps, and measured only three of these pressures: P_i , P_s , and P_d . This omission limits K evaluations based on pump tests to K_n and K_{td} . Fortunately, the theory works quite well under this limitation, largely because the throat and diffuser K s are additive ($K_{td} = K_{th} + K_{di}$) in the $N(M)$ equations.

In regard to Item 1 above, Table 2 shows the range and recommended values for the K s which appear in the theoretical model equations.

Table 2 recommendations assume that only P_i , P_s , and P_d are utilized; if this is the case, it is necessary to assume that $K_{en} = 0$, as indicated. A finite value of K_{en} in Eqs. (15)–(17)

TABLE 2 Recommended values for K friction-loss coefficients

| | Range | Rec. Values | References |
|----------|---------|-------------|------------|
| K_n | .04–1.0 | .05 | 3, 10, 11 |
| K_{en} | — | 0 | ditto |
| K_{td} | .17–.40 | .20 | ditto |

**FIGURE 4** Response of L/JL operating pressure ratio N_{op} and operating flow ratio M_{op} to jet pump design area ratio b

increases the slope of the theoretical $N(M)$ curve at low M values. At operating M values, however, this effect is negligible.

Finding b as a Function of N_{op} or M_{op} Figure 4 presents $N_{op}(b)$ and $M_{op}(b)$ for the recommended K friction coefficients of .05, 0, and .20. The Figure 4 curves are cross-plots of M_{op} values ($=\frac{2}{3}M_{mep}$) and associated N_{op} values. (To find M_{mep} value at b , Eqs. (17)–(18) spreadsheets of $\eta(M)$ and $N(M)$ were prepared for b values covering the range .05–.6; these numerical values are provided in Table 3.) Graphical representation of the L/JL pump characteristics as shown in Figure 4 is useful in estimating b values when the jet pump application fixes N or M , and hence b . Example 3 illustrates the utility of Figure 4.

Straight-Line $N(M)$ Approximation Early investigators (see Reference 2) noted a nearly linear behavior of N versus M . A “straight-line” approximation for $N(M)$ based on the axis intercepts N_o and M_o would, of course, be useful. A true parabolic efficiency curve would result so $M_{\text{mep}} = \frac{1}{2} M_o$, and M_o is easily found. Unfortunately, the degree of this linearity varies with area ratio b . At about $b = .12$, the N curve is in fact a straight line. But as b is increased, the $N(M)$ curve is increasingly concave down so the $\eta = MN$ “parabolic” curve is increasingly skewed to the left. The converse is true at very small b values. Accordingly, the straight-line approximation is not recommended for use in designing LjL jet pumps. Instead, the Eqs. (17) and (18) theoretical model should be solved and charted for each b -value pump under consideration. Again, the recommended operating flow ratio $M_{\text{op}} = \frac{2}{3} M_{\text{mep}}$.

Longitudinal Dimensions of the LjL Jet Pump One-dimensional theory includes dimensions perpendicular to flow, but provides no guidance for longitudinal shapes/profiles. Two hardware dimensions of key importance must be taken from the literature or determined experimentally: nozzle-to-throat spacing “sp” and mixing throat length “L.” Both are expressed in terms of throat diameters; sp/D_{th} and L/D_{th} . Recommended values are given as follows.

NOZZLE-THROAT SPACING Many experimental searches for optimum sp have been reported. Sanger and Vogel both found (see References 10 and 12) that maximum efficiency (slightly above 40% for Reference 10) is obtained with $\text{sp}/D_{\text{th}} = 0$, using nozzles with an external concave tapering, leading to a thin lip at the outlet. This configuration matches the theoretical model: The jet discharges to pressure P_o at the throat inlet, and thus the normal jet loss was eliminated. But a zero spacing promotes cavitation, even with a thin-lipped nozzle tip, and certainly with the rounded-nose exterior profile used in Reference 4. Sanger found that retracting nozzles a distance of about one diameter provided good cavitation resistance and at only a small loss in efficiency. Other investigators have found that performance is insensitive in the range of $\text{sp}/D_{\text{th}} = 0.5$ –2 diameters, and that small spacings do promote cavitation. (see Reference 1). *It is recommended that LjL jet pumps be designed with $\text{sp}/D_{\text{th}} = 1$.*

MIXING-THROAT LENGTH The parallel-walled throat should be long enough to allow complete mixing, but throat lengths should be as short as possible to minimize frictional losses. L/D_{th} values as well as length (a venturi shape) ranging 1.0 to 10 have been reported for LjL pumps. Several factors affect optimum throat length:

- When sp/D_{th} is finite—true for most jet pumps—mixing takes place in the distance (sp plus part or all of L , the mixing-throat length); thus, sp and L are interrelated. Sanger (see Reference 10) found that optimum sp/D_{th} increased from 0 to 2.3, for pumps with $L/D_{\text{th}} = 7.5$ and 3.5 respectively.
- The primary-flow nozzle affects required L : Long tapered nozzles promote boundary-layer build-up producing jets that delay mixing, increasing required L . Multi-hole nozzles and swirl-inducing nozzles promote mixing and reduce required length L , but pump efficiency suffers because of increased nozzle-flow losses. (See “Primary-Flow Nozzle Design.”)
- Pump area-ratio b can affect optimum throat length. Small- b pumps operate with high flow ratios and throat lengths of $L/D_{\text{th}} = 8$ were required. For pumps with larger b values, throat lengths of four diameters sufficed (see Reference 13).
- The gas compressor jet pump (LjG) requires longer throats, as high as 10–30 throat diameters (see Reference 7).

$L/D_{\text{th}} = 6$ is recommended for general LjL design use. Efficiency of the proposed pump may subsequently be improved by optimizing L (experimentally) for the given pump and duty.

PRIMARY-FLOW NOZZLE DESIGN A short-entry internally-convex profile similar to the ASME metering flow nozzle, is recommended for the LjL pumps. Avoid long conical nozzles.

Liquid-jet flow from a sharp-edged orifice mixes readily and is recommended for the LJG gas compressor (see Reference 7). The annular-nozzle liquid-jet pump has been investigated. In this configuration the secondary flow is axial, surrounded by the primary flow at the throat entrance. This arrangement is advantageous in pumping sticky secondary fluids because it prevents wall contact of the sticky fluid at the throat entry (see Reference 1). An obvious disadvantage is the increased nozzle frictional loss caused by flow of the primary fluid over the comparatively large surface area of the annular nozzle.

THROAT-INLET CONTOUR Many jet pumps reported in the early literature had long (small-convergence-angle) conical sections connecting the suction chamber to the throat, and usually including a sudden wall angle change at the throat entry. Later developments led to the short (large-convergence-angle) entry, well rounded at the throat. The long (small-angle) conical entry is wrong because its proximity to the nozzle exterior throttles the secondary flow and because it promotes cavitation. Secondly, a long approach section increases wall friction (reflected in a high K_{en} if it is measured). A short entry to the throat and a well-rounded profile connecting the suction chamber and throat is recommended.

Laboratory Flow Tests Performance testing of LJL pumps requires a facility with appropriate instrumentation, pumps, flow meters, and control valves. The flow rates Q_1 and Q_2 , and at least three static pressures, P_i , P_s , and P_d , must be recorded at each test point. In addition, it is recommended that the throat section(s) contain static pressure taps for measurement of P_i and P_t . Jet pump test data will then permit measurement of K_{en} , K_{th} and K_{di} . For on-design operation, these K s vary little, if at all, with change in flow ratio M . Departures of $K(M)$ from nominal levels serve to reveal otherwise hidden problems. One example is that K_{th} will change if an increase in flow ratio causes mixing to extend/persist from the throat section into the diffuser (inadequate throat length). Another example is that a sudden rise in K_{di} may indicate diffuser-wall separation.

LIQUID-JET LIQUID (LJL) PUMP DESIGN EXAMPLES

Equations (1), (3), (5) and (7) will model jet pumps for LJL, LJG and LJGL configurations. Equations (1), (11–19) apply specifically to the LJL jet pump. The three numerical examples provided here are for this widely used pump only. LJG and LJGL liquid-jet pumps are less common: please see References 5, 6 and 7.

Example 1 Design a jet pump to handle 50 gpm (11.36 m³/h) of water at 80°F (26.7°C) from a suction at 14.7 psia atmospheric pressure (101.325 kPa) to discharge at 40 psi (275.8 kPa). Determine the required primary flow rate, jet nozzle pressure and dimensions of the jet pump.

Solution: For best efficiency, select $b = .25$. From Table 2, adopt $K_n = 0.5$, $K_{id} = .20$, and $K_{en} = 0$. Eq. (17) then produces $N(M)$. A computer spreadsheet table for Eqs. (17) and (18) showing output values based on increments of M is recommended, for example, see Table 1. As shown by the bottom line in Table 1, the $M_{nep} = 1.104$ (found by successive approximations using the spreadsheet program). The operating flow ratio is $M_{op} = \frac{2}{3}M_{nep} = .676$. The spreadsheet program at this M_{op} produces the N_{op} (.428) and η (28.934%) values shown in Table 1, second line from the bottom. From Eq. 19 $(P_d - P_s)/P_i - P_s = N/(N + 1)$, so and $P_i - P_s = (1.428/.428)40 = 1.3346$ psi (920.212 kPa). Thus $P_i = 1.3346 + 14.7 = 148.16$ psia (1021.56 kPa). Liquid jet pumps—with very few exceptions—operate with the nozzle tip withdrawn from the throat entry by one throat-diameter or more. The nozzle tip experiences a discharge pressure close to P_s , not P_o , and “jet loss” thus occurs. For this jet loss condition, Eq. (1) changes to $(P_i - P_s) = Z(1 + K_n)$. The jet velocity head $Z = 1.3346/1.05 = 1.2710$ psi (876.35 kPa).

CAVITATION-LIMITED FLOW RATIO M_L The flow ratio M_L is now evaluated using Eq. (20) to answer the question: will $M_{op} = .676$ avoid pump cavitation? The area ratio $c = (1 - .25)/$

.25 = 3. For the secondary fluid (water at 80°F, 26.7°C), $P_v = .506$ psia (3.49 kPa). The conservative value of $\sigma = 1.35$ is used in Eq. (20) as follows:

$$M_L = 3\sqrt{\frac{14.7 - .506}{1.35 \times 1.2710}} = .863$$

Because $M_{op} (.676) < M_L (.863)$, this pump will not cavitate at the specified operating condition.

JET PUMP DIMENSIONS $Q_1 = Q_2/M_{op} = 50/.676 = 73.96$ gpm (16.8 m³/h) = 73.96/(7.481 × 60) = .165 ft³/s. Longitudinal dimensions: $sp/D_{th} = 1.0$, thus $sp = .937$ in (23.81 mm). For $L/D_{th} = 6$, $L = 6 \times .937 = 5.62$ in (142.75 mm). A diffuser with an included angle of 5° (conservative) and area ratio $a = .224$ would have length of approximately 12 in (304.8 mm). A shorter diffuser may be desirable, but kinetic-energy leaving losses will be higher.

EXAMPLE 1 USING OTHER AREA RATIOS An infinite number of different jet pumps can be designed to handle the Example 1 duty of pumping 50 gpm at 40 psi discharge pressure. The previous numerical example ($b = .25$) was repeated using $b = .1, .4$, and $.6$. Table 4 compares the results of these four b -ratio pumps. In each case the design is based on $M_{op} = \frac{2}{3}M_{mep}$; the assumed K values and calculation procedure are similar for the four pumps.

The expression CR% in Table 4 indicates the $(M_L - M_{op})/M_{op}$ % separation of operating flow ratio M_{op} and the limiting flow ratio M_L ; the larger this number, the better. For this constant-duty example ($Q_2 = 50$ gpm and $P_d = 40$ psi), Table 4 shows that cavitation resistance can be improved by using a larger b ratio, i.e., the $(M_L - M_{op})/M_{op}$ % figure increases with b . Note that at the smallest b value (.1), the cavitation value (sixth column) is CR = -5.3%: this indicates that $M_{op} > M_L$, and this pump *would* encounter cavitation: $b = .1$ should not be used at these M_{op} and σ values. A redesign of the pump suction chamber (nozzle-external profile and throat-inlet profile) leading to an improvement in cavitation coefficient σ could render the $b = .1$ pump usable (the value $\sigma = 1.35$ used previously is conservative). For example, an improvement to $\sigma = 1.0$ would raise M_L to 2.0. With this change, a $b = .1$ pump could be used, cavitation-free.

Table 4 shows two other important facts: (1) The $b = .25$ pump provides the highest efficiency, even though all four are designed to operate at $\frac{2}{3}M_{mep}$, i.e., each at a similar position on the efficiency curve specific to that pump. (2) Small b -value pumps operate at large nozzle pressure-drops ($P_i - P_s$) and with small Q_1 primary-values. Conversely, high b -value pumps operate with small nozzle pressure-drops, but use a large flow rate Q_1 . The pumps have in common similar expenditures of energy ($Q_1 \times$ pressure change, and allowing for efficiency differences) to handle the duty, which is the same in all four cases. In some design problems the nozzle-pressure—or possibly the primary-fluid flow volume—might outweigh the importance of mechanical efficiency. Table 4 shows how an adjustment in b might be used to achieve improved cavitation, albeit with efficiency sacrifices.

REDUCING THE FLOW RATIO M_{op} TO COPE WITH CAVITATION For a given b -value L_JL jet pump, a reduction in M_{op} offers a way to improve cavitation resistance. The $b = .1$ pump used

[For SI conversions: lb/in² \times 6.89 = kPa; gpm \times 0.277 = m³/h; in \times 25.4 = mm]

in this example is examined for the effects of M_{op} reduction, in Table 5. The conditions for all four pumps in Table 5 are $b = .1$, and again, $K_n = .05$, $K_{id} = .2$, $K_{en} = 0$. The Table 5 top line is $M_{op} = 1.808$, followed by three .5 decrements of M_{op} . The corresponding N_{op} and η_{op} values are found from successive approximations using the spreadsheet based on Eqs. (17) and (18). The M_L values are calculated from Eq. (20). The CR% cavitation merit figure (5th column) is the same as used in Table 4. Table 5 shows that while a $b = .1$ pump at $M_{op} = 1.808$ flow ratio will cavitate, the three lower M_{op} cases all exhibit increased CR% cavitation resistance. In Table 5, M_L (4th column) changes little with M_{op} ; the cavitation improvements largely result from the decreases in M_{op} . The primary flow rate Q_1 increases markedly, and the nozzle pressure decreases somewhat as M_{op} is reduced. Compared with adjustment in b , cavitation avoidance by reducing M_{op} has obvious disadvantages: Efficiency is severely reduced, and the pump size (see D_n , 8th column) must be increased to handle the larger flow Q_1 .

In summary, every jet pump design should be evaluated for cavitation resistance. The CR% index used here ($(M_L - M_{op})/M_{op} \%$) is suggested if several options are to be compared. Otherwise, the simpler test $M_{op} < M_L$ is adequate. Cavitation resistance for a given pump duty can be improved by increasing the area ratio b , or by reducing M_{op} of a particular pump, or by reducing the cavitation coefficient σ by improved internal design.

Example 2 Design a jet pump to lift 80°F (27.67°C) water to 20 ft (6.1m) to discharge at an atmospheric pressure of 14.7 psia or 34 ft of water (10.3 m). A mechanical pump provides the primary flow stream; fluid power available at the jet pump is 10 kW. Find the secondary flow Q_2 , and pump dimensions.

Solution: Assume the same K values used in Example 1. Again select $b = .25$, for maximum efficiency. Eq. 17 (via spreadsheet program) produces $M_{nep} = 1.014$ and $M_{op} = \frac{2}{3}(1.014) = 0.676$, where $N_{op} = .428$ and $\eta = 28.93\%$. $P_s = (34-20) = 14$ ft water abs. (4.261 m abs.) at the suction chamber. And $P_s = 14 \times 1.934 \times 32.174/144 = 6.05$ psia (41.72 kPa). $(P_d - P_s) = (14.7 - 6.05) = 8.65$ psi (59.64 kPa). From Eq. 19, $(P_i - P_s) = (P_d - P_s)(N + 1)/N$, so that $(P_i - P_s) = (14.7 - 6.05)(1.428/.428) = 28.86$ psi (199 kPa). $P_i = 28.86 + 6.05 = 34.91$ psia (40.7 kPa). $Z = (P_i - P_s)/(1 + K_n) = 28.86/1.05 = 27.486$ psi (189.52 kPa).

Cavitation-Limited Flow Ratio M_L Limiting flow ratio (Eq. 20)

$$M_L = 3\sqrt{\frac{6.05 - .506}{1.35 \times 27.486}} = 1.16$$

Because $M_{op} (.676) < M_L (1.16)$, the proposed LJJL jet pump will not cavitate.

JET PUMP DIMENSIONS Power in = $Q_1(P_i - P_d)$; Q_1 = power in/ $(P_i - P_d)$, where $(P_i - P_d) = (34.91 - 14.7) = 20.21$ psi. With 10 kW treated here as the net "fluid" power available at the nozzle. (In Figure 2 the jet and mechanical pumps are at the same elevation)

FIGURE 5 Jet and centrifugal pump system, for Example 3

$$Q_1 = \frac{10 \times 7.481 \times 60}{1.356 \times 10^{-3} \times 144 \times 20.21} = 1137.42 \text{ gal/min (258.6 m}^3\text{/h)}$$

(conversion factors 7.481 gal/ft³ and 1.356 watts/ft-lb/s were used previously)

Secondary flow $Q_2 = 1137.42 \times .676 = 768.9 \text{ gpm (174.6 m}^3\text{/h)}$.

Nozzle area:

$$A_n = \frac{Q_1}{V_n}, \text{ where } V_n = \sqrt{2 \times 27.476 \times \frac{144}{1.934}} = 64 \text{ ft/s (19.51 m/s)}$$

$$A_n = (768.9 \times 144) / (64 \times 7.481 \times 60) = 3.85 \text{ in}^2 (24.84 \text{ cm}^2)$$

Nozzle diameter:

$$D_n = \sqrt{3.85 \times \frac{4}{3.1416}} = 2.22 \text{ in (56.39 mm)}$$

Example 3 As shown in Figure 5, a surface-mounted centrifugal pump requires a NPSH of 10 ft (3 m) of water, and the centrifugal-pump discharge pressure is 60 psi (414 kPa) at 100 gpm (22.7 m³/h). Water at 50°F (10°C) is to be lifted 50 ft (15.2 m). Design the jet pump including dimensions, and find the primary and secondary flow rates.

Solution: The jet pump's placement and centrifugal-pump discharge and inlet pressures determine all three jet-pump operating pressures, and hence the pressure characteristic N .

$$P_i = 60 \text{ psi} + (50 + 1) \times 1.94 \times 32.17/144 = 82.1 \text{ psi (566.1 kPa)}$$

$$P_s = 1 \times 1.94 \times 32.17/144 = .433 \text{ psi (299 kPa)}. P_d = (50 + 10) \times$$

$$1.94 \times 32.17/144 = 26 \text{ psi (179.27 kPa)}. N_{op} = (P_d - P_s) / (P_i - P_d) = .456.$$

To estimate the b level which will operate at this N , enter Figure 4 with $N_{op} = .46$: the corresponding $b = .27$, and $M_{op} = .62$. Estimate b values should be confirmed—and adjusted if necessary—using a spreadsheet solution based on Eqs (17) and (18). In this case the

spreadsheet results are $N_{op} = .461$, $b = .265$, $M_{op} = .626$, and $\eta = 28.8\%$. The cavitation check and calculation of dimensions follow next. *Note:* This solution is a first estimate because piping frictional losses have not been included in the calculations. Second and third—if necessary—calculations must include the pressure losses in the piping connecting the two pumps.

CAVITATION LIMITED FLOW RATIO M_L . Jet velocity head $Z = (P_i - P_s)/(1 + K_n) = (82.1 - .433)/(1 + .05) = 77.78$ psi (536.29 kPa).

For water at 50°F (10°C), $P_v = .178$ psia (1.23 kPa)

$$M_L = c \sqrt{\frac{P_s - P_v}{\sigma}} \times Z = 2.774 \sqrt{\frac{15.133 - .178}{1.35}} \times 77.78 = 1.047$$

Because $M_{op} (.626) < M_L (1.047)$, the jet pump will not cavitate at the operating point.

JET PUMP DIMENSIONS $Q_1 + Q_2 = 100$ gpm (19.71 m³/h), and $Q_2/Q_1 = .626$, so $Q_1 = 61.5$ and $Q_2 = 38.5$ gpm (12.12 and 7.59 m³/h). $A_n = Q_1/V_n$.

Jet velocity:

$$V_n = \sqrt{\frac{2Z}{\rho_1}} = \sqrt{\frac{2 \times 77.8}{1.94}} = 107.46 \text{ ft/s (32.75 m/s).}$$

$$Q_1 = 61.5/7.481 \times 60 = .137 \text{ ft}^3/\text{s (13.97 m}^3/\text{h)}$$

$$\text{Nozzle area } A_n = (.137/107.46)144 = 1.87 \text{ in}^2 (1.187 \text{ cm}^2).$$

Nozzle diameter:

$$D_n = \sqrt{\frac{4 \times A_n}{\pi}} = \sqrt{\frac{4(.184)}{3.1416}} = .483 \text{ in (12.27 mm).}$$

Throat diameter:

$$D_{th} = \frac{D_n}{\sqrt{b}} = \frac{.483}{.515} = .938 \text{ in (23.83 mm)}$$

Nozzle-throat spacing recommended: $sp/D_{th} = 1$, hence $sp = .938$ in (23.83 mm)

Mixing-throat length recommended: $L/D_{th} = 6$, hence $L = 6 (.938) = 5.63$ in (143 mm)

Centrifugal-Jet-Pump Interactions Oil- and water-well pumping are major applications of L/JL pumps. Compact jet pumps, lowered down the bore hole near to or below the liquid surface, are powered by primary flow supplied from a mechanical pump located above, at the earth's surface. The jet pump pressurizes the surface pump's suction preventing cavitation. The design of a combination pump system normally requires designing for operation at the intersection of the two pumps' operating curves (Refs. 17, 18, and 19) and of course inclusion of frictional losses (neglected in Example 3) in the associated piping. One operating point (100 gpm at 60 psi) in Example 3 represented the centrifugal pump. The 60 psi discharge pressure of the centrifugal pump and the vertical placement fixed the jet pump's N_{op} operating point. This in turn determined the jet pump's b value. Consider now a change in the centrifugal pump to one providing 100 gpm at 100 psi (22.7 m³/h at 6.89 kPa): the jet pump's N_{op} (and b) would be reduced, and M_{op} raised. Details are omitted here, but the resultant area ratio would be about $b = .167$, which would provide $M_{op} = 1.09$, a considerable increase over $M_{op} = .626$, as found in Example 3.

SIGNIFICANCE OF ON-DESIGN OPERATING CONDITIONS

With reference to Figure 3, assume that the pump is operating on-design at $M_{op} = \frac{2}{3}M_{mep}$; that is, on the left branch of the efficiency “parabola.” Primary flow rate Q_1 and suction pressure P_s are constant. If the back pressure P_d is then *reduced*, the secondary flow rate Q_2 (and hence M_{op}) will rise and pressure ratio N_{op} will fall. The new operating points will move to the right, along the characteristic curves for N and η . This increased-flow response to lowered P_d will end when cavitation-limited flow ratio M_L is reached, assuming the NPSH is low enough to allow cavitation. Any further reduction of P_d will cause the operating points to leave the N and η theoretical curves on paths vertically downward as shown by the dashed line in Fig. 3. Consider next the same initial condition (on design: $M_{op} = \frac{2}{3}M_{mep}$) followed by an *increase* in jet-pump discharge pressure P_d . In response, the secondary flow Q_2 (and hence M) will decrease, the N_{op} and η_{op} operating points moving left along the pump's N and η characteristic curves. Ultimately, increasing the back-pressure will result in reaching the $M = 0$ point, where $N = N_o$. (See Table 1, showing $N = N_o = .680$ at $M = 0$.)

Mechanical efficiency is important in most jet pump installations. Two low-efficiency situations that should obviously be avoided are

- Throttling the pump discharge pressure (to raise the P_d to the design point) wastes energy. Design P_d should match the pressure of the system into which the pump is to discharge.
- Operating the LJL pump with a discharge pressure P_d less than the design P_d (same Q_1 and P_s) will yield more Q_2 flow ($M > M_{op}$) and slightly higher efficiency. But such an increase in M may reach the cavitation point, that is, where $M = M_L$, causing a marked departure of actual/measured operating points downward from the N and η characteristic curves.

OTHER JET PUMP APPLICATIONS

Virtually any fluid can be pumped by the liquid-jet pump. Suspensions of solids in a liquid can be handled with the LJL analysis given by incorporating the “S” density-ratio term. In extreme cases, slurry pumping may also be affected by slip velocity and solids concentration (see References 1 and 15).

Steam jet pumps are found in the earliest literature (see Reference 1). Analyses have usually combined one-dimensional treatment with shock-wave compressibility phenomena. Theory has not contributed to the longitudinal dimensions problem, as is the case with liquid jet pumps. Advances in applying two- and three-dimensional flow theory have contributed to understanding low Mach-number mixing length requirements. Air/air jet pump theory and performance have been compared (see Reference 16). Analysis of high-velocity compressible-flow gas-jet pumps has been less successful.

Design of a two-pump combination system (illustrated by Examples 2 and 3) required system operation at an intersection of the mechanical- and jet-pump characteristic curves, selected so both pumps operate at or near their maximum efficiency points (see References 17, 18 and 19). And the system design must of course include consideration of the pressure losses that will occur in the piping connecting the two pumps.

SECTION 4.2

JET PUMP APPLICATIONS

ALEX M. JUMPETER

This section contains extensive design and application experience for a variety of jet pump configurations. Although this section concentrates on eductors (termed L/JL jet pumps in Section 4.1), experience with other motive (primary) and secondary fluids is also included. The theoretical developments of Section 4.1 are the basis for what is presented here, the dimensional design ratios being generally within the ranges mentioned therein. Therefore, the only theory in this section is the empiricism that is utilized in the examples and applications presented. Refer to Section 4.1 for further explanation.

DEFINITION OF TERMS

A definition of standard ejector terminology is as follows:

| | |
|-----------------------|---|
| <i>Ejector</i> | General name used to describe all types of jet pumps that discharge at a pressure intermediate between motive and suction pressures. |
| <i>Eductor</i> | A liquid jet pump using a liquid as motive fluid. |
| <i>Injector</i> | A particular type of jet pump that uses a condensable gas to entrain a liquid and discharge against a pressure higher than either motive or suction pressure; principally, a boiler injector. |
| <i>Jet Compressor</i> | A gas jet pump used to boost pressure of gases. |
| <i>Siphon</i> | A liquid jet pump utilizing a condensable vapor, normally steam, as the motive fluid. |

EDUCTORS

Design The elements of an eductor design are shown in Figure 1. Quantities involved are defined as follows:

P_1 = static pressure upstream, lb/ft² (N/m²)

P_s = static pressure at suction (nozzle tip), lb/ft² (N/m²)

V = velocity, ft/s (m/s)

γ_1 = specific weight (force) of motive fluid, lb/ft³ (N/m³)

$$\frac{P_1 - P_s}{\gamma_1} = \text{operating head, ft (m)}$$

P_s = static pressure at suction, lb/ft² (N/m²)

P_2 = static pressure at discharge, lb/ft² (N/m²)

γ_2 = specific weight (force) of mixed fluids, lb/ft³ (N/m³)

$$\frac{P_2 - P_s}{\gamma_2} = \text{discharge head, ft (m)}$$

The head ratio R_H is defined as the ratio of the operating head to the discharge head:

$$R_H = \frac{(P_1 - P_s)/\gamma_1}{(P_2 - P_s)/\gamma_2} = \frac{(P_1 - P_s)\gamma_2}{(P_2 - P_s)\gamma_1} \quad (1)$$

Because ratios are involved, it is convenient to replace specific weight with specific gravity:

$$R_H = \frac{(P_1 - P_s)(\text{sp. gr.}_2)}{(P_2 - P_s)(\text{sp. gr.}_1)} \quad (2)$$

When the suction and motive fluids are the same, no gravity correction is required and Eq. 2 becomes

$$R_H = \frac{H_1 - H_s}{H_2 - H_s} \quad (3)$$

where $H_1 - H_s$ = operating head, ft (m)

$H_2 - H_s$ = discharge head, ft (m)

Entrainment relates the mass (flow rate) of motive fluid and suction fluid:

FIGURE 1 Eductor elements and terminology

M_1 = mass of motive (primary) fluid, slugs (kg)

M_s = mass of suction (secondary) fluid, slugs (kg)

$$R_w = \frac{M_s}{M_1} = \text{the weight operating ratio} \quad (4)$$

The volume ratio R_q is then simply

$$\frac{Q_s}{Q_1} = R_w \frac{\text{sp. gr.}_1}{\text{sp. gr.}_2} \quad (5)$$

where Q_s = suction (secondary) flow in volumetric units

Q_1 = motive (primary) flow in volumetric units

The performance of eductors is expressed here in terms of R_H and R_w , utilizing an empirical relationship that involves an efficiency factor ϵ as follows:

$$R_w = \epsilon \sqrt{R_H} - 1 \quad (6)$$

This equation is used to calculate the motive quantity or pressure from the operating parameters. This nozzle and diffuser diameters are calculated from the equation $Q = wAV$, using suitable nozzle and diffuser entrance coefficients. The principal problems in design concern the size and proportions of the mixing chamber, the distance between nozzle and diffuser, and the length of the diffuser. Eductor designs are based on theory and empirical constants for length and shape. The most efficient units are developed from calculated designs that are then further modified by prototype testing.

Figure 2 shows this factor plotted against $NPSH$ (net positive suction head) for a single-nozzle and annular-nozzle eductor. In an annular-nozzle eductor, the motive fluid is introduced around the periphery of the suction fluid, either by a ring of nozzles (Figure 15) or by an annulus created between the inner wall of the diffuser and the outer wall of the suction nozzle (Figure 14). The $NPSH$ is the head available at the centerline of the eductor to move and accelerate suction fluid entering the eductor mixing chamber. $NPSH$ is the total head in feet (meters) of fluid flowing and is defined as atmospheric pressure minus suction pressure minus vapor pressure of suction or motive fluid, whichever is higher.

Increased viscosity of motive or suction fluid increases the frictional and momentum losses and therefore reduces the efficiency factor of Figure 2. Below 20 cP, the effect is minimal (approximately 5% lowering of ϵ). Above this value, the loss of performance is more noticeable and empirical data or pilot testing is used to determine sizing parameters.

FIGURE 2 NPSH versus efficiency factor (Schutte and Koerting)

FIGURE 3 Estimating operating ratios for liquid jet eductors. An eductor can be designed for only one head point (Schutte and Koerting)

Figure 3 shows the operating ratio R_w versus the head ratio R_H for various lift conditions. The efficiency factor has been incorporated into this curve.

The final size of the eductor is determined by the discharge line and is based on normal pipeline velocities, which are usually 3 to 10 ft/s (0.9 to 3 m/s). Figure 4a and 4b are used for estimating eductor size. To illustrate the use of Figures 3 and 4, consider the following example.

EXAMPLE 1 It is desired to remove 100 gpm (22.7 m³/h) of water at 100°F (38°C) from a pit 20 ft (6.1 m) deep. Discharge pressure is 10 lb/in² (0.69 bar*) gage. Motive water is available at 60 lb/in² (4.1 bar) gage and 80°F (26.6°C). The eductor is to be located above the pit. Find the eductor size and motive water quantity required.

*1 bar = 10⁵ Pa. For a discussion of bar, see *SI Units—A Commentary* in the front matter.

FIGURE 4A Sizing curve (gpm $\times 0.227 = \text{m}^3/\text{h}$; ft $\times 0.3048 = \text{m}$)

Solution To use Figure 3, it is necessary to determine the $NPSH$ and the head ratio R_H . The centerline of the eductor is chosen as the datum plane, and $NPSH$ is taken to be atmospheric pressure minus suction lift minus vapor pressure at 100°F (38°C):

FIGURE 4B Sizing curve (continued)

$$\text{in USCS units} \quad NPSH = 34 \text{ ft} - 20 \text{ ft} - 1.933 \text{ inHg} \left(\frac{13.6}{12} \right) = 11.81 \text{ ft}$$

$$\text{in SI units} \quad NPSH = 10.36 \text{ m} - 6.1 \text{ m} - 49 \text{ mmHg} \left(\frac{13.6}{1000} \right) = 3.59 \text{ m}$$

Because motive and suction are the same fluid, it is convenient to work in feet (meters) rather than pounds per square inch (bar), and

$$P_1 = 60 \text{ lb/in}^2 \text{ gage} = 138.6 \text{ ft H}_2\text{O} \text{ (4.1 bar} = 42 \text{ m)}$$

$$P_2 = 10 \text{ lb/in}^2 \text{ gage} = 23.1 \text{ ft H}_2\text{O} \text{ (0.69 bar} = 7 \text{ m)}$$

$$P_s = -20 \text{ ft} \text{ (-6.1 m)}$$

Then

$$\text{in USCS units} \quad R_H = \frac{138.6 - (-20)}{23.1 - (-20)} = \frac{158.6}{43.1} = 3.68$$

$$\text{in SI units} \quad R_H = \frac{42 - (-6.1)}{7 - (-6.1)} = 3.68$$

Enter Figure 3 at $R_H = 3.68$ and $NPSH = 11.81$ (3.59 m); read $R_w = 0.48$. Because there is no gravity correction,

$$\text{in USCS units} \quad R_w = R_q = \frac{0.48 \text{ gal suction}}{\text{gal motive}}$$

$$\text{in SI units} \quad R_w = R_q = \frac{0.48 \text{ m}^3 \text{ suction}}{\text{m}^3 \text{ motive}}$$

The same result can be obtained by using the efficiency factor from Figure 2. Then R_w is $0.77\sqrt{R_H} - 1 = 0.48$ and the required motive fluid is

$$\text{in USCS units} \quad \frac{100 \text{ gpm suction}}{0.48} = 208 \text{ gpm at } 60 \text{ lb/in}^2 \text{ gage}$$

$$\text{in SI units} \quad \frac{22.7 \text{ m}^3/\text{h}}{0.48} = 47.3 \text{ m}^3/\text{h at } 4.1 \text{ bar gage}$$

Discharge flow is

$$\text{in USCS units} \quad 208 + 100 = 308 \text{ gpm}$$

$$\text{in SI units} \quad 47.3 + 22.7 = 70.0 \text{ m}^3/\text{h}$$

The size is obtained from Figure 4. Enter Figure 4b at $Q_2 = 308 \text{ gpm}$ (70 m³/h) and discharge head ($H_2 - H_3$) = $23.1 - (-20) = 43.1 \text{ ft}$ [$7 - (-6.1) = 13.1 \text{ m}$]; read eductor size of 4 in (102 mm) based on the discharge connection.

NOTE: If there were any appreciable length of run on the discharge line, it would be necessary to calculate the pressure drop in this line and recalculate the eductor size after adding the line loss to the discharge head required. Frictional losses on the suction side must also be included. In the example chosen, however, 100 gpm (22.7 m³/h) in a 4-in (102-mm) suction line 20 ft (6.1 m) long will have negligible frictional loss, less than 0.25 ft (0.08 m) H₂O.

FIGURE 5 Characteristic performance of an eductor

Performance Characteristics Figure 5 illustrates the performance characteristics of eductors. Note the sharp break in flow rate below the design point. For this reason, all eductors are not designed for a peak efficiency. It is often advantageous to have a wide span of performance with lower efficiencies rather than a peak performance with very limited range. (See Section 4.1; where, also, the validity of assuming a straight-line head-vs.-suction flow characteristic is discussed.)

Applications Beside the obvious advantages of being self-priming, having no moving parts, and requiring no lubrication, eductors can be made from any machinable material in addition to special materials, such as stoneware, Teflon,[®] heat-resistant glass, and fiberglass. The applications throughout industry are too numerous to mention, but some of the more common will be discussed here. The type of eductor is determined by the service intended.

GENERAL PURPOSE EDUCTORS Table 1 is a capacity (flow rate) table for a general purpose eductor used for pumping and blending. This type of eductor, illustrated in Figure 6, has a broad performance span rather than a high peak efficiency point. Standard construction materials for this type of eductor are cast iron, bronze, stainless steel, and PVC. Typical uses include cesspool pumping, deep-well pumping, bilge pumping aboard ship, and condensate removal.

The following problem illustrates the use of Table 1.

EXAMPLE 2 Pump 30 gpm (6.81 m³/h) of water from a sump 5 ft (0.61 m) below ground. Discharge to drain at atmospheric pressure. Motive water available is 40 lb/in² (2.8 bar) gage.

Solution Enter left side of Table 1 at 5 ft (1.5 m) suction lift and 0 lb/in² (bar) gage discharge pressure. Read horizontally across to 40 lb/in² (2.8 bar) gage operating water pressure. Read 9.6 gpm (2.18 m³/h) suction and 7.3 gpm (1.66 m³/h) operating fluid. These values are obtained in a 1-in (25.4-mm) eductor with a capacity ratio of 1.0.

To determine the capacity ratio of the required unit, divide the required suction by the quantity handled in 1-in (25.4-mm) eductor:

$$\text{in USCS units} \quad \text{Capacity ratio} = \frac{30}{9.6} = 3.13$$

$$\text{in SI units} \quad \text{Capacity ratio} = \frac{6.81}{2.18} = 3.13$$

Source: Schutte and Koerting.

Referring to the bottom of Table 1, a 2-in (50.8-mm) eductor with a capacity ratio of 4.0 is obtained. The required motive flow is then

in USCS units $4(7.3) = 29.2 \text{ gpm}$
in SI units $4(1.66) = 6.64 \text{ m}^3/\text{h}$

and the suction capacity is

in USCS units $4(9.6) = 38.4 \text{ gpm}$
in SI units $4(2.18) = 8.72 \text{ m}^3/\text{h}$

A $1\frac{1}{2}$ -in (38-mm) unit can handle 2.89 times the values in Table 1, or 27.7 gpm (6.3 m³/h) suction when using 21 gpm (4.8 m³/h) motive water at 40 lb/in² (2.8 bar) gage. If suction flow rate is not critical, some capacity can be sacrificed in order to use a smaller and therefore lower-cost eductor. If optimum performance is desired, it is necessary to size a special eductor using Figures 3 and 4.

Figure 7 illustrates more streamlined versions for higher suction lifts or applications involving the handling of slurries. This type of eductor is often used to remove condensate from vessels under vacuum. The advantage is that eductors require only 2 ft (0.61 m) *NPSH* and, being smaller than mechanical pumps, save considerable space. Further, a partial vapor load is much less likely to vapor-lock a jet pump because the venturi tube

FIGURE 6 General purpose eductor (Schutte and Koerting)

FIGURE 8 Sparger nozzle (Schutte and Koerting)

FIGURE 9 Motive flow rate of Sparger nozzles ($\text{gpm} \times 0.227 = \text{m}^3/\text{h}$; $\text{lb}/\text{in}^2 \times 0.0689 = \text{bar}$) (Schutte and Koerting)

minimizes the expansion effect of flashing vapor. Sizing is done in the manner illustrated in Example 1, using Figures 3 and 4.

MIXING EDUCTORS Although any eductor is inherently a mixing device, some are specifically designed as mixers. They are used to replace mechanical agitators and are located inside the tank containing the fluid to be agitated. Figure 8 illustrates the simplest type of eductor, the *Sparger nozzle*. These units entrain a volume of suction fluid that is approximately three times the volume of motive fluid. A 20-lb/in² (1.4-bar) drop across the nozzle is recommended for proper mixing. Figure 9 shows the motive flow rates for this type

TABLE 2 Motive flow rates of tank mixing eductors, gpm^a

of eductor. Sparger nozzles are normally used for shallow tanks, whereas the following tank mixer described is preferred for deeper vessels.

Figure 10 illustrates a type of eductor called a *tank mixer*. It is installed under the tank containing the fluid to be agitated. Motive capacities are shown in Table 2. The units are usually custom-designed for a specific entrainment ratio, the required capacity being determined by the quantity of tank fluid, the ratio of mixture desired, and the depth of the tank being agitated.

EXAMPLE 3 It is desired to blend recycled tank fluid into a tank 20 ft (6.1 m) deep in a volume ratio of 1 motive to 1.5 suction. The tank contains 7500 gal (28.4 m³), and it is desired to turn over the tank in 30 min. The motive pump will deliver 60 lb/in² (4.14 bar) gage at the eductor nozzle. What size mixing eductor is needed?

Solution The 500 gal (28.4 m³) turned over in 30 minutes is equivalent to 250 gpm (56.8 m³/h). Because the motive fluid in this case is recycled from the tank, both motive and suction fluid contribute to the tank turnover. In the ratio of 1.5 suction to 1 motive fluid, the motive quantity required to attain a circulation rate of 250 gpm (56.8 m³/h) is 100 gpm (22.7 m³/h). To select the size, it is necessary to obtain the differential pressure across the nozzle orifice of the eductor. Because the eductor is below the tank, the net driving head is 60 lb/in² gage - 20/2.31 = 51.35 lb/in² (4.14 - 6.1/10.2 = 3.54 bar) gage across the nozzle. Enter Table 2 and interpolate between 50 and 60 lb/in² (3.4 and 4.1 bar) gage. A $1\frac{1}{2}$ -in (38-mm) eductor will pass only 73 gpm (16.6 m³/h), whereas a 2-in (51-mm) eductor will pass 129 gpm (29.3 m³/h). The selection would then be a 2-in (51-mm) mixing eductor.

SPINDLE PROPORTIONING EDUCTORS Another type of mixing eductor is illustrated in Figure 11. Typical applications of this type include mixing hydrocarbons with caustic, oxygen, or copper chloride slurries; producing emulsions; and proportioning liquids in chemical process industries. In critical applications, the regulating spindle is sometimes fitted with a diaphragm operator to achieve close control. Table 3 shows operating pressures and flow rates on several typical applications for units of this type.

SAND AND MUD EDUCTORS Figure 12 illustrates a sand and mud eductor used for pumping out wells, pits, tanks, sumps, and similar containers where there is an accumulation of

sand, mud, slime, or other material not easily handled by other eductors. With this type of eductor, the bottom of the pressure chamber is fitted with a ring of agitating nozzles that stirs the material in which the jet is submerged to allow maximum entrainment. Relative capacities for this type of eductor are shown in Table 4, which is used in the same manner as Table 1. The required suction flow is divided by the suction capacity selected from Table 4 under the appropriate motive pressure. This value is the capacity ratio. From the table, select the eductor by choosing the next highest capacity ratio. Actual flow rates are then determined by multiplying the values in the table by the capacity ratio of the eductor selected. Maximum discharge head is read from the table.

SOLIDS-HANDLING EDUCTORS Figure 13 illustrates a specific type of eductor called a *hopper eductor*, made for handling slurries or dry solids in granular form and used for eject-

ing sludges from tank bottoms, pumping sand from filter beds, and washing or conveying granular materials. Typical construction is cast iron with hardened steel nozzle and throat bushings. In operation, the washdown nozzles are adjusted to provide smooth flow down the hopper sides, thus preventing bridging of the material being handled and also sealing the eductor suction against excess quantities of air. Without this seal, the capacities shown in Table 5 should be divided by approximately 3. Table 6 shows typical materials handled by this eductor and their bulk density. Use of the capacity table for hopper eductors is similar to use of Tables 1 and 4, except the suction quantities required are expressed in cubic feet (cubic meters). Capacity ratio is determined by dividing the value in the table into the required suction flow, and the next largest size eductor is selected.

Another type of solids-handling eductor is illustrated in Figure 14. This *annular-orifice eductor* is used where the material being handled tends to agglomerate and gum up when wetted and has been used successfully for handling and mixing hard-to-wet solids. In this

unit, intimate mixing occurs in the throat, and the device is virtually clogproof. Normally this unit is installed directly over the tank into which the mixture is discharged. Table 7 shows capacities for this type of unit.

Capacity Table 7 is similar to Table 5, and the selection method is the same as discussed previously.

MULTINOZZLE EDUCTORS Figure 15 illustrates an annular multinozzle eductor designed for special applications where the suction fluid contains solids or semisolids. It is used primarily for large flows at low discharge heads. Because these units have relatively large air-handling capacities, they are well suited for priming large pumps, such as dredging pumps, where air pockets can cause these pumps to lose their prime. These eductors are designed by using the basic equations for head ratio. The appropriate efficiency factor is selected from Figure 2, and the volumetric flow ratio is calculated. Figure 4 is used to size the eductor after discharge flow has been determined.

DEEP-WELL EDUCTORS The eductor illustrated in Figure 16 is typical of those used in conjunction with a mechanical pump for commercial and residential water supply from a deep well. The eductor is used to lift water from a level below barometric height up to a level where the suction of the motive pump at the surface can lift the water the remaining distance.

In operation, the eductor is fitted with hoses connected to the suction and discharge of the motive pump and dropped into the well casing. An initial prime is required, which is maintained by the foot valve at the suction of the eductor. When the surface pump is activated, pressure water through the eductor entrains water from the well, lifting it high enough to enable the mechanical pump to carry it to the surface. A bypass valve at the surface diverts the suction quantity to a receiving tank.

Capacities of these units depend on the depth of the well and the centrifugal pump. The standard commercial unit has 1-in (25-mm) pressure and 1¼-in (32-mm) discharge connections and is available with a variety of nozzle and diffuser combinations for use with standard centrifugal pumps at varying depths. The following example illustrates how to calculate this type of unit.

FIGURE 14 Annual eductor (Schutte and Koerting)

EXAMPLE 4 A centrifugal pump with a capacity of 100 gpm (22.7 m³/h) at a total discharge head of 150 ft (45.7 m) and requiring 10 ft (3.05 m) NPSH is available to operate an eductor to pump water at 50 ft (15.2 m) below grade. Find the quantity of water that can be delivered at 60 lb/in² (4.1 bar) gage (see Figure 17).

Solution The available operating head is 138.6 ft + 50 ft – frictional loss (42.2 + 15.2 – frictional loss). As a first assumption, the frictional loss is ignored and the head ratio is 188.6/40.83 = 4.62 (57.4/12.38 = 4.62). From Figure 2 at NPSH 33.6 ft (10.24 m), $\varepsilon = 0.9$ and

$$R_w = R_q = 0.9 \sqrt{4.62} - 1 = 0.934$$

(from Eqs. 5 and 6)

With Q_R fixed at 100 gpm (22.7 m³/h),

TABLE 7 Relative capacities (flow rates) of annual eductors

| Capacity of standard 1½-in (38.1-mm) mixing eductor, 5 lb/in² (0.34 bar) gage discharge pressure | | | | | | |
|---|-------------|-------------|-------------|-------------|-------------|--|
| Motive pressure, lb/in²(bar) gage | 30 (2.1) | 40 (2.8) | 60 (4.1) | 80 (5.5) | 100 (6.9) | |
| Entrainment, ft³/h (m³/h) | 2.6 (0.07) | 7.1 (0.20) | 17.9 (0.51) | 22.0 (0.62) | 23.8 (0.67) | |

FIGURE 15 Multinozzle eductor (Schutte and Koerting)

FIGURE 16 Centrifugal-jet pump combination

FIGURE 17 Centrifugal-jet pump for Example 4

$$\text{in USCS units} \quad Q_1 = \frac{100}{1 + R_q} = \frac{100}{1.934} = 51.7 \text{ gpm}$$

$$\text{in SI units} \quad Q_1 = \frac{22.7}{1.934} = 11.7 \text{ m}^3/\text{h}$$

The motive line size is now chosen by selecting a reasonable velocity and frictional loss. Choosing a 2-in (51-mm) pipe size, velocity is 5.57 ft/s (1.70 m/s) and frictional loss is 6.1 ftH₂O (1.86 mH₂O). The revised operating head becomes 188.6 – 6.1 = 182.5 ft (57.4 – 1.86 = 55.6 m) and

$$\text{in USCS units} \quad R_q = 0.9\sqrt{182.5/40.83} - 1 = 0.9$$

$$\text{in SI units} \quad R_q = 0.9\sqrt{55.6/12.38} - 1 = 0.9$$

then $Q_1 = 100/1.9 = 52.6 \text{ gpm}$ ($22.7/1.9 = 11.9 \text{ m}^3/\text{h}$). (This value is close enough so that a third trial is not necessary.) The suction flow that can be delivered is then

$$\text{in USCS units} \quad 100 - 52.6 = 47.4 \text{ gpm}$$

$$\text{in SI units} \quad 22.7 - 11.9 = 10.8 \text{ m}^3/\text{h}$$

PRIMING EDUCTORS—WATER-JET EXHAUSTERS Eductors are often used as priming devices for mechanical pumps. In this application, the eductor is used to remove air rather than water. Liquid jets are not well suited for pumping noncondensables; therefore, the capacities are low. However, the volume being primed is usually small, and so the low capacity is not a factor. When larger volumes are involved, such as condenser water boxes, it is more feasible to use an exhauster. The water-jet eductor of Figure 6 is converted to a water-jet exhauster by replacing the jet nozzle with a solid-cone spray nozzle. Evacuating rates and capacity tables for such a unit are shown in Figure 18 and Table 8. Eductors have approximately one-fifth the air-handling capacities of water-jet exhausters when supplied with similar motive quantities and pressures.

EXAMPLE 5 From Figure 18 and Table 8, determine size and water consumption to exhaust 15 standard ft³/min (0.42 m³/min) of air at 20 inHg (508 mmHg) abs discharging to atmosphere using 60 lb/in² (4.14 bar) gage motive water at 80°F (27°C).

Solution Enter Figure 18 at 80°F (27°C) (1); read horizontally to the suction pressure 20 inHg (508 mmHg) abs (2); project vertical line to 60 lb/in² (4.14 bar) gage motive pressure (3); project a horizontal line for the capacity of a 1-in (25-mm) exhauster (4); divide desired flow by the capacity of a 1-in (25-mm) unit, which is 1.9 standard ft³/min, (0.054 m³/min), to find capacity ratio: $15/1.9 = 7.9$ ($0.42/0.054 = 7.9$).

The capacity ratio table shows that a 3-in (76-mm) exhauster with a capacity ratio of 9.0 is required. The motive water quantity from Table 8 is 86 gpm (19.5 m³/h). *Note:* Table 8 gives water consumption at 15 inHg (381 mmHg) abs; because flow varies as the square of pressure differential across the nozzle, the exact flow is obtained as follows:

Nozzle upstream pressure:

$$\text{in USGS units} \quad 60 + 14.7 = 74.7 \text{ lb/in}^2 \text{ abs}$$

$$\text{in SI units} \quad 4.14 + 1.01 = 5.15 \text{ bar abs}$$

Nozzle downstream pressure:

$$\text{in USCS units} \quad 20 \text{ inHg abs} \left(\frac{14.7 \text{ lb/in}^2}{30 \text{ inHg}} \right) = 9.8 \text{ lb/in}^2 \text{ abs}$$

FIGURE 18 Capacity curve of water-jet exhausters (Schutte and Koerting)

in SI units $508 \text{ mmHg abs} \left(\frac{1.01 \text{ bar}}{762 \text{ mmHg}} \right) = 0.67 \text{ bar abs}$

Operating differential:

in USCS units $74.7 - 9.8 = 64.9 \text{ lb/in}^2$

in SI units $5.15 - 0.67 = 4.48 \text{ bar}$

Table differential:

$$\text{in USCS units} \quad 74.7 - 15 \left(\frac{14.7}{30} \right) = 67.35 \text{ lb/in}^2$$

$$\text{in SI units} \quad 5.15 - 381 \left(\frac{1.01}{762} \right) = 4.64 \text{ bar}$$

Actual flow:

$$\text{in USCS units} \quad 86 \left(\frac{64.9}{67.35} \right)^{1/2} = 84.4 \text{ gpm}$$

$$\text{in SI units} \quad 19.5 \left(\frac{4.48}{4.64} \right)^{1/2} = 19.2 \text{ m}^3/\text{h}$$

SIPHONS

Operation As previously defined, the term *siphon* refers to a jet pump utilizing a condensable vapor to entrain a liquid and discharge to a pressure intermediate between motive and suction pressure. The principal motive fluid is steam.

In an eductor, the high-pressure motive fluid enters through a nozzle and creates a vacuum by jet action, which causes suction fluid to enter the mixing chamber. The siphon of Figure 19 is identical to the eductor of Figure 6 except that, unlike the eductor, the siphon motive nozzle is a converging-diverging nozzle to achieve maximum velocity at the nozzle tip. The velocity is supersonic at this point. The motive fluid is condensed into the suction fluid on contact and imparts its energy to the liquid, thus impelling it through the diffuser. The diffuser section is the same as an eductor diffuser, and it converts the velocity energy to pressure at the discharge. To achieve maximum performance, the siphon nozzle must be expanded to the desired suction pressure in order to achieve the highest possible velocity. Because negligible radiation losses are encountered, the siphon is 100% thermally efficient in that the heat in the incoming water plus the heat in the operating steam must equal the heat of the mixture plus its mechanical energy. Furthermore, the momentum of the incoming water plus the momentum of the expanded steam is equal to the momentum of the discharge mixture less impact and frictional losses.

It is important that the motive steam be condensed in the suction liquid prior to the throat for proper operation. If condensation does not occur, full available energy is not transferred. Furthermore, energy must be expended to recompress the uncondensed

FIGURE 19 Standard siphon (Schutte and Koerting)

FIGURE 20 Annular siphon (Schutte and Koerting)

steam. For this reason, discharge temperature cannot exceed the boiling point at the discharge pressure. The fact that energy is required to recompress any uncondensed steam explains why air is a very poor motive fluid for liquid pumping.

STANDARD SIPHONS Tables 9 and 10 illustrate the capacity and operating characteristics of standard siphons. These tables are similar to the eductor capacity tables. To size a unit, read the suction capacity of a 1½-in (38-mm) unit from Table 9 at the appropriate motive steam pressure, suction lift, and discharge head. Divide the desired suction flow by this capacity to find the capacity ratio. From Table 10, find the unit with the next largest capacity ratio. Read the motive steam required under the proper motive pressure.

Standard materials of construction are cast iron, bronze, stainless, steel, and Pyrex®. If desired, special capacity ratios can be achieved by using a custom-designed unit. Sizes over 6 in (152 mm) can be fabricated of any suitable material.

ANNULAR SIPHONS Figure 20 illustrates an annular siphon. This unit is identical to the eductor of Figure 14 except that steam is the motive fluid. Capacity Table 11 is used in the same manner as previous examples. This type of siphon is used when inline flow is desired or when the suction liquid contains some solids. Units are available in cast iron through an 8-in (203-mm) size. Special materials or fabricated designs are also available.

OTHER JET PUMP DEVICES

Air Siphons As previously mentioned, air is a very poor motive fluid for entraining a liquid because energy must be expended in compressing the air back to the discharge pressure. There are, however, applications where it is necessary to sample a liquid with no dilution.

Small units (less than 1 gpm, 0.23 m³/h) can be supplied for limited discharge pressures, as indicated by Figure 21. With air as the motive fluid, the suction liquid can be very close to its boiling point and only a very slight *NPSH* is required.

When air is used as a motive fluid, the smaller sizes operate more efficiently because the air is more intimately mixed with a suction fluid. In larger sizes, the tendency is for the fluid to be discharged in slugs because intimate mixing does not readily occur. This has a detrimental effect on the performance and especially on available discharge head.

Air-Lift Eductors Air-lift pumps are frequently used for difficult pumping operations. Compressed air is forced into the bottom of a pipe submerged in the liquid to be pumped. The expanding air, as it rises up the pipe, entrains the suction fluid.

If compressed air is not available, it is possible to lift water higher than 34 ft (10 m) with the use of an eductor-air-lift combination. Figure 22 illustrates the suction capacity

FIGURE 21 Air pumping liquid (Schutte and Koerting)

FIGURE 22 Suction capacity of eductor-air-lift combination ($\text{gpm} \times 0.227 = \text{m}^3/\text{h}$)

of a 2-in (51-mm) eductor drawing water from a 50-ft (15-m) depth and discharging it to the atmosphere. In operation, an air line from the atmosphere enters the suction pipe near the water level. As the eductor creates a vacuum in this line, atmospheric pressure forces air into the suction pipe. After it is in the line, the rising air carries the suction fluid to the surface and both fluids are discharged to the atmosphere through the eductor.

No sizing data are presented because this type of pump is best specified according to specific conditions.

Boiler Injectors The boiler injector is a jet pump utilizing steam as a motive fluid to entrain water, and it is used as a boiler feedwater heater and pump. It differs from a siphon in that the discharge pressure is higher than either motive or suction pressure. This is achieved by the double-tube design shown in Figure 23. In operation, the lower nozzle is activated by pulling the handle partway back. The lower jet creates a vacuum in the chamber, causing water to be induced into the unit. When water is spilling out the overflow, the handle is drawn back all the way. This closes the overflow and simultaneously admits motive steam to the upper jet. This second jet, which is of the straight or forcing type, picks up the discharge from the first jet and imparts a velocity to the water through the discharge tube. The energy contained is sufficient to open the check valve and discharge against the boiler pressure.

The now obsolete steam locomotives were the largest users of this type of injector. Principal use at present is as a backup to a regular boiler-feed pump. Capacity Table 12 illustrates the range of capacities available for the double-tube injector.

MATERIALS OF CONSTRUCTION

SECTION 5.1

METALLIC MATERIALS OF PUMP CONSTRUCTION (AND THEIR DAMAGE MECHANISMS)

COLIN O. McCAUL
RONALD S. MILLER

The requirements for a successful pump installation are *performance* and *life*. Performance is the rating of the pump head, capacity, and efficiency. Life is the total number of hours of operation before one or more pump components must be replaced to maintain an acceptable performance. The initial performance is the responsibility of the pump manufacturer and is inherent in the pump design. Life is primarily a measure of the resistance of the materials of construction to corrosion, erosion, wear, and other factors that can influence the materials when the pump has been placed in service. The need to maximize reliability and extend the pump life makes the selection of appropriate materials of construction crucial.

The selection of materials that are both cost-effective and technically suitable for the application requires a knowledge not only of the pump design and manufacturing processes, but also of the engineering properties of the material, particularly its corrosion and wear resistance properties when subjected to the conditions encountered in the pump. Sufficient information is available in the corrosion and metallurgical literature as well as from the experience of pump manufacturers to make appropriate material choices for virtually any pumping application.

It is known that several factors lead to a long pump life. These include

- Neutral liquids at near-ambient temperatures
- Appropriate material selections for pumps in aggressive services
- The absence of abrasive particles
- Continuous operation at or near the maximum efficiency capacity of the pump
- An adequate margin of available *NPSH* over *NPSH* required as stated on the manufacturer's rating curve
- A low velocity (developed head/rotative speed)

Pumping installations that satisfy all these criteria will have a long life. A typical example would be a waterworks pump. Some waterworks pumps with bronze impellers

and cast-iron casings have a life of 50 years or more. At the other extreme might be a chemical pump handling a hot corrosive liquid with abrasive particles carried in suspension. The life of this pump might be measured in months rather than in years, despite the fact that construction was based on the most resistant materials available.

Most pumping applications fall somewhere between these two extremes. The pump designer needs to be familiar with the various types of degradation that can affect the components of the pump and reduce its useful life. These can be grouped into the general categories of corrosion, wear, and fatigue, with corrosion and wear being the predominant life-limiting mechanisms.

TYPES OF CORROSION

General Corrosion General corrosion is corrosion that proceeds without an appreciable localization of attack. This type of corrosion occurs on metals or alloys that do not develop an effective passive film on the surface. Usually, the corrosion mechanism is oxidation with the formation of metal oxide corrosion products. General corrosion is most often encountered in pumps with carbon steels and copper base alloys. Cast irons also experience a specialized form of general corrosion, known as *graphitic corrosion*, which will be considered separately.

Carbon steel does not develop a protective oxide film and will corrode at a rate dependent upon several characteristics of the water or other fluid, including temperature, oxygen content, pH, and fluid chemistry. Several empirical indices based on water chemistry exist and can be used to calculate the relative corrosivity of natural waters to carbon steel and similar ferrous alloys. The Langelier Index is best known. The rate of corrosion is also very dependent on velocity and increases with an increasing velocity. In most pump applications, with the notable exception of hydrocarbons, the corrosion rate of carbon steel is too high for this material to provide a useful life. However, carbon steel is frequently used, particularly in vertical pumps, with some form of protective coating to prevent corrosion. Coal tar epoxy is a preferred coating for many water services.

Copper alloys, including both brasses and bronzes, are also subject to general corrosion in the water applications where they are most commonly used in the pump industry. The corrosion rate will be increased by the presence of small amounts of sulfides in the water. Copper alloys gradually develop a protective copper oxide corrosion film in most applications. The corrosion rate gradually decreases over time as this film develops. The rate of general corrosion varies with the specific type or grade of copper alloy. Among the alloys commonly used in pumps, nickel aluminum bronzes have the lowest corrosion rate and best tolerance for higher velocities.

The general corrosion of a Ductile Ni-Resist casing from a vertical pump is shown in Figure 1. A metallographic cross section was removed to show the depth of the corrosion attack.

FIGURE 1 A small fragment of Ductile Ni-Resist from the lower casing of a vertical pump. The microstructure is also shown on the right side of this figure, illustrating the depth of the corrosion's penetration. This is a classic example of general corrosion (right photo at 100 \times).

Dealloying Dealloying is the preferential removal of one phase from a multi-phase alloy, or one element from a material. Several types of dealloying occur in the pump industry. One of the most common is the graphitic corrosion of gray cast iron. This material is low cost, easy to machine, and well suited for a variety of applications, especially in the waterworks industry. It is probably the most widely used material in the pump industry.

Gray cast iron corrodes by a fundamentally different mechanism than carbon steel or ductile cast iron. The structure of gray cast iron consists of interconnected graphite flakes in a matrix that is predominantly iron. In the presence of an electrolyte, which is usually water, a galvanic cell is established between the iron and graphite. The iron corrodes, and the corrosion products are largely flushed away with the fluid passing through the pump. The original casting is gradually reduced to a porous graphite structure that may contain some iron oxide corrosion product. This is frequently referred to as *graphitization*. The surface of a gray iron casting that has suffered graphitic corrosion will retain its original shape and dimensions, but the surface will be largely graphite, which can be cut with a knife. The casting will lose some fraction of its mechanical properties and become increasingly susceptible to brittle failure, resulting from modest shock or impact loads. This is also the corrosion mechanism for Ni-Resist in seawater. Figure 2 shows the interface between the sound base metal and the graphitized front.

It is important to recognize that the rate of graphitic corrosion varies with the water chemistry, and that this type of corrosion can occur in both fresh and salt waters. The high conductivity of salt water corresponds to a higher corrosion rate. Graphitic corrosion will proceed at a slower pace in waters that have a high mineral content. Minerals tend to plug the graphitic layer on the surface, sealing off the base metal from exposure to the fluid, thereby reducing the corrosion rate.

As the surface of a cast-iron component, such as a pump casing, gradually graphitizes, the galvanic relationships with other components within the pump will be altered. It has been observed that the bronze impeller originally supplied in a cast-iron pump handling seawater will provide a significantly longer life than bronze impellers that are installed after the pump has been in service for several years. The reduced life of the replacement impellers is caused by an altered galvanic relationship with the pump casing. Initially, the casing was cast iron, which is anodic to a bronze impeller. With time, as the casing graphitizes, it gradually becomes cathodic, due to the influence of the graphite. The bronze impeller is now the anode and corrodes at a much higher rate. This example highlights the influence that graphitic corrosion can have on other components within the pump and the importance of carefully selecting materials for use in conductive fluids, such as salt water.

Several other types of dealloying can also occur in pumps. Brass and bronze alloys containing more than about 14 percent zinc are subject to a form of dealloying known as *dezincification*. The zinc is preferentially corroded from the matrix of the material, leaving a spongy, copper-rich residue. Dezincification can occur either uniformly in a shallow layer

FIGURE 2 The interface between the advancing graphitized front and the sound base metal. Graphitic corrosion propagates along the path of the graphite flakes (50 \times).

FIGURE 3 The dealloying of a vertical turbine pump impeller. Note the change in color across the cross section. The unaffected bronze (light color) material is surrounded by a dezincified layer (1.3 \times).

over the surface of the casting or as a distinct plug confined to a small area. Plug-type dezincification is a more serious problem because the plug is weak and will cause leakage if it penetrates a pressure boundary, but it should be emphasized that copper alloys containing less than 14 percent zinc are not susceptible to this form of corrosion. Consequently, the requirement often imposed upon pump manufacturers for zinc-free bronzes to avoid dezincification is without technical justification. Figure 3 shows the dealloying of an impeller.

The final type of dealloying that occasionally occurs in pumps is dealuminification in aluminum bronzes. These are metallurgically complex materials. Some compositions can form an aluminum-rich phase that can be preferentially corroded in aggressive fluids, especially seawater. The detrimental phase can be mitigated by a special heat treatment known as *temper annealing*. This heat treatment must be specified by the designer for susceptible compositions, because it is not a mandatory requirement of national material specifications. The chemistry of some aluminum bronze alloys from Europe has been adjusted to preclude the formation of the detrimental aluminum-rich phase without the need for the temper annealing heat treatment. The temper anneal can serve as a stress relief operation for fabricated aluminum bronze structures, which is a secondary benefit for products in this category.

Galvanic Corrosion *Galvanic corrosion* refers to the corrosion that occurs when one alloy is electrically coupled to another and exposed in a conductive liquid. Usually, the corrosion rate of the more noble alloy will be less than if it were exposed uncoupled. The corrosion rate of the less noble material will be greater than if it were exposed uncoupled.

Several factors influence the rate of galvanic corrosion of both metals. This corrosion is greatly influenced by the conductivity of the fluid. In a fluid such as fresh water, which has a low conductivity, galvanic corrosion will be less severe and generally confined to the immediate location where the metals contact one another. However, in a highly conductive fluid, such as seawater, galvanic corrosion will be more severe and will occur over a wider area. The pump designer needs to consider the possibility of such corrosion when using dissimilar metals in a conductive fluid.

Galvanic corrosion problems in seawater and other conductive fluids can be avoided by the careful use of materials. Galvanic corrosion is related to the area ratios of the coupled metals. It is always desirable to have the area of the anode, or less noble metal, equal to or greater than that of the more noble metal. In this way, the additional corrosion experienced by the less noble metal will be spread over a relatively large area and will not be excessive because of being coupled. An example of the effective use of this galvanic relationship involves centrifugal pumps having a Ni-Resist casing and austenitic stainless steel internals. This combination is often specified for seawater services. The Ni-Resist is

anodic to the stainless steel and will protect it from localized corrosion when the pump is shut down and contains stagnant water. The area of Ni-Resist is considerably larger than that of stainless steel. The increased galvanic corrosion of the Ni-Resist is spread over a large area and is negligible.

The amount of corrosion that will occur in a galvanic couple also depends on the freely corroding potentials of the coupled metals. Less corrosion-resistant metals, such as zinc, cast iron, and steel will usually have more negative potentials when measured against a standard reference electrode. More corrosion-resistant metals, such as stainless steels, will have less negative potentials.

The corrosion potentials for many commonly used engineering alloys in slowly moving seawater are shown in Table 1. The alloys are listed in the order of the potential that they exhibit in flowing seawater. Certain alloys (indicated by solid colored boxes preceding the name of the alloy) in low-velocity or poorly aerated water and at shielded areas may become active and exhibit a potential near -0.5 volts. The extent of galvanic corrosion that will occur when two metals are electrically coupled will depend on the potential difference between the metals. The corrosion rate of zinc coupled to stainless steel will increase dramatically because of the large potential difference between these two metals. A nickel aluminum bronze coupled to austenitic stainless steel will experience little galvanic corrosion because the potentials of these two metals are close to one another. The pump designer needs to be aware of the corrosion potentials of dissimilar metals used in conductive fluids in order to avoid unanticipated galvanic corrosion problems.

The use of coatings can decisively alter the galvanic relationships in a pump. If the more anodic component, such as a steel casing, is coated, one can expect a high rate of corrosion at those locations where the coating eventually begins to fail. This will be caused by a very unfavorable area ratio, with a small area of exposed carbon steel coupled to a large area of some more noble metal, such as stainless steel or bronze. For this reason, coatings should be employed with caution in pumps handling conductive fluids that are constructed of dissimilar metals. It is generally advisable in these applications not to coat the anodic component. Figure 4 documents the galvanic corrosion on the interior diameter of a carbon steel flange connected to a stainless steel shroud. The accelerated corrosion is due to the unfavorable ratio of stainless steel to carbon steel in this component.

Stress Corrosion Cracking *Stress corrosion cracking* (SCC) is a particularly dangerous form of corrosion because it is not easily detected before it has progressed to such an extent that it can cause sudden catastrophic damage. Although relatively uncommon in pumps, it can occur in several classes of materials. The pump designer should be aware of the potential combinations of material and environment that can cause SCC.

Stress corrosion requires that several factors be present. These include tensile stress, which can be either residual or applied, a susceptible material, an environment capable of causing stress corrosion, and time.

The materials used in the pump industry that may experience SCC include austenitic and martensitic stainless steels, some copper base alloys, and, occasionally, Ni-Resist. The austenitic stainless steels are susceptible to stress corrosion in aqueous chlorides at temperatures above about 140°F (60°C). Cast alloys, which contain some fraction of ferrite in the microstructure, are significantly more resistant to stress corrosion than their wrought counterparts. The possibility of cracking is increased in situations where chlorides are concentrated, as by evaporation. High residual stress, often present in as-welded structures, also enhances the possibility of cracking. Increasing nickel content in austenitic stainless alloys enhances the resistance to SCC. The high nickel grade, commonly known as Alloy 20, is often used in chemical applications where the optimum resistance to stress corrosion is necessary. The SCC of austenitic stainless steels in pumps is relatively uncommon.

Martensitic stainless steels are susceptible to cracking in the presence of hydrogen sulfide and is often referred to as *sulfide stress corrosion cracking* (SSC). These steels, particularly CA-15 and CA-6NM, are commonly used in pumping applications in oil production and refining where hydrogen sulfide can be present. SCC can be avoided by giving these materials a special heat treatment intended to reduce hardness below a certain threshold level, below which cracking will not occur. This has also been correlated to the yield strength of a material. It is often seen in literature that ferrous materials used

TABLE 1 Corrosion potentials in flowing seawater (8–13 ft/s, 50–80°F/2.4–4.0 m/s, 10–26°C)

in these services should have a hardness no greater than 22 R_c or a yield strength no higher than 90,000 lb/in² (620MPa). Technical standards, including API 610 and NACE MR-01-75, can be used to specify appropriate requirements for martensitic steels, which will be used in environments containing hydrogen sulfide.

FIGURE 4 Galvanic corrosion is evident on this pump section. Note the high corrosion rate on the interior diameter of the carbon steel flange that is attached to the stainless steel shroud.

Copper alloys are susceptible to SCC in the presence of ammonia, although considerable variations take place in the susceptibility of the various types of bronzes, with aluminum bronzes being the most resistant. Polluted natural waters can contain ammonia, and for this reason, bronze pumps are usually not a good choice for these applications.

High-strength manganese bronzes are susceptible to cracking in natural waters. Cast impellers in these alloys have been known to suffer severe cracking. Residual stress in the casting may also be sufficient to induce cracking. These alloys should not be used in pumps because of their susceptibility to such problems.

Ni-Resist is an austenitic cast iron that contains 15 to 20% nickel. This material is commonly used in large, seawater vertical pumps. Experience has shown that it is subject to SCC, especially in the diffuser section of these pumps, unless the castings are furnace stress-relieved. This must be specified by the purchaser, as it is not a requirement of national material specifications.

Hydrogen Embrittlement Hydrogen damage is a form of environmentally assisted failure that results from the combined action of hydrogen and residual or applied tensile stress. Hydrogen damage to specific alloys or groups of alloys manifests itself in many ways, such as cracking, blistering, hydriding, or as a loss of tensile ductility. Collectively, these various forms of damage are often referred to as *hydrogen embrittlement*.

Damage caused by hydrogen is occasionally encountered in pumps. Some plating processes, such as chrome plating, which is often used to rebuild pump shafts, generate hydrogen. This hydrogen can enter the surface of the metal. Microscopic cracks can occur in higher strength steels (greater than a 90,000-lb/in² or 620-MPa yield strength). Abusive grinding can work-harden the surface of lower strength steels and increase the probability that hydrogen will cause cracking. Microscopic cracks resulting from hydrogen damage act as stress risers and can propagate failure catastrophically by mechanical fatigue. This problem can be avoided by utilizing proper grinding practices before plating. Higher strength steels should be baked, to drive off hydrogen, immediately after plating.

Hydrogen can also be introduced into metals during welding. In order to avoid the hydrogen damage associated with welding, ferritic and martensitic steels should be welded with low hydrogen electrodes. Coated electrodes should be baked, in accordance

with manufacturer's instructions, prior to usage in order to drive off moisture, which is the major source of hydrogen contamination of welds.

Microbiologically Induced Corrosion Living organisms can promote corrosion in many different environments. A variety of biological organisms thrive in both aerobic and anaerobic environments. Corrosion attributable to microbiological activity occurs most frequently in stagnant water, which remains in a pump when it is shut down for an extended length of time.

Sulfate-reducing bacteria are found in many waters. They will form slimy, reddish hemispherical shaped mounds or colonies on cast iron or carbon steel. These are known as *tubercles*. If scraped off, there will invariably be a saucer-shaped pit beneath the tubercle. The inside of the pit will contain a wet, black deposit. The pitting is caused by traces of sulfuric acid excreted by the bacteria. This type of corrosion will usually not result in premature failure.

Several more serious types of microbiologically induced corrosion afflict stainless steels. A certain class of metal ion concentrating/oxidizing microbes appears to concentrate ferric and manganic chlorides, both of which are potent pitting agents. These bacteria form colonies preferentially at welds in austenitic stainless steels and are capable of causing severe pitting corrosion in a relatively short time. This problem has been encountered in a variety of equipment in both salt and fresh water. It is often discovered only when the welds begin leaking. Pumps employing welded stainless steel fabrications can be afflicted by this problem if permitted to sit idle with stagnant water, either fresh or salt, for an extended period. Biocides can be used to mitigate this problem in some instances.

Finally, the decay of biological organisms can generate hydrogen sulfide, which adversely affects the protective oxide film on copper base alloys. The enhanced biological activity in warmer tropical waters, especially under stagnant conditions, can impair the corrosion resistance of bronzes and reduce the threshold velocity at which accelerated corrosion will occur. Bronzes should be used with caution in applications where microbiological activity is anticipated and the possibility of extended shutdowns is possible.

Intergranular Corrosion This infrequent type of corrosion preferentially attacks a material at the grain boundaries. This is caused by local chemical differences such as the chrome-depleted regions of an austenitic stainless steel. Bronze alloys susceptible to this type of corrosion include aluminum bronzes, silicon bronzes, Muntz metal, and admiralty metal. Two things are necessary: a sensitized material and a corrosive media, such as seawater. Sensitization can occur during heat treatment or more commonly during weld repair. This type of corrosion often leads to corrosion-assisted fatigue cracks when cyclic loading is present.

The improper heat treatment of 300 series austenitic stainless steels can result in sensitization to intergranular corrosion. Sensitization occurs when stainless steels that contain more than .03% carbon are held at temperatures between 800 and 1550°F (between 425 and 850°C). At these temperatures, chrome carbides precipitate along the grain boundaries, resulting in chrome depletion in the adjacent areas. These adjacent areas have reduced corrosion resistance. Austenitic stainless steels contain approximately 16 to 18% chrome. The chromium content in the areas surrounding a chrome carbide particle can drop below the 12% necessary to maintain a passive state. A galvanic cell is set up with a large cathode (grains) and a small anode (grain boundaries). In this undesirable scenario, corrosion occurs along the anodic grain boundaries. The extent of the corrosion damage depends on the length of time held within the sensitization temperature range. The degree of sensitization is a function of the carbon content; the higher the carbon content, the shorter the period of time the material can be held within this range without sensitization occurring. A graph of the temperature versus time for various carbon contents illustrates this point in Figure 5. Intergranular corrosion of an improperly heat-treated stuffing box cover is shown in Figure 6.

Austenitic stainless steels can also be sensitized during normal welding procedures. Care must be taken to avoid the sensitization range during welding followed by proper post-weld heat treatment when necessary.

Sensitization can be avoided or corrected by several methods:

- Heat the material to a temperature high enough to dissolve the chrome carbides, typically 1900 to 2100°F (1040 to 1150°C), followed by rapid cooling through the sensitization range. Localized heat treatment of welded areas will not desensitize a material.
- Use a stainless steel that is stabilized by the addition of niobium or titanium. These two elements will tie up the carbon, thus preventing chrome carbides.
- Reduce the carbon content to a low level (less than .03 percent). The lower the carbon content, the longer it takes chrome carbide precipitation to occur.

When austenitic stainless steels are necessary in the pump industry, materials commonly used in services where intergranular attack is anticipated include 316L, 304L, CF-3, and CF-3M. Intergranular corrosion is not a concern in alloys containing 25% or more chromium.

Cavitation Erosion Cavitation erosion is primarily a mechanical process, although it acts synergistically with corrosion and is often considered with other forms of corrosion. Cavitation erosion can be defined as metal removal from the surface caused by high

FIGURE 5 Time-temperature sensitization curves as determined by the Strauss Test for 18-8 stainless steel. Note that a low carbon grade of stainless (0.03% C) requires five to 10 hours exposure, while a standard grade (0.08%) need only minutes of exposure time.

FIGURE 6 The surface of a stuffing box cover that experienced intergranular corrosion due to sensitization. The grains are clearly evident on the interior of the bore as well.

FIGURE 7 Cavitation erosion of an impeller, indicated by the porous appearance of cavitated regions on the surface

stresses associated with the collapse of vapor bubbles in the fluid. Cavitation occurs in a pump when the local pressure of the fluid is reduced to the vapor pressure. In a multi-stage pump, vapor bubbles form in the low-pressure areas at the impeller inlet and are swept by the flow into regions of higher pressure where they collapse. A great many bubbles may form and collapse in a small area, producing many microjets of high kinetic energy. The energy released by the bubble collapse is expended as impact loading on the metal surface. This situation is aggravated if protective oxide films are present because these are damaged, exposing fresh metal to the corrosive action of the fluid. This cyclic loading eventually causes the formation of microscopic fatigue cracks. These cracks propagate and intersect, resulting in the removal of metal from the surface and the characteristic spongy or porous appearance of cavitation damage. An example of a cavitated impeller is shown in Figure 7.

Although every effort should be made in the design and application of centrifugal pumps to prevent cavitation, it is not always possible to do so at capacities less than the rated maximum efficiency capacity of the pump. It must be recognized that at a low flow operation, the stated *NPSH* required curve is not usually sufficient to suppress all cavitation damage. The stated *NPSH* required is that needed to produce the head, capacity, and efficiency shown on the rating curve. At low flows, some cavitation damage should be expected. It may be impractical to supply an *NPSH* that would suppress all cavitation at these low flows, as it could be many times that it is required at the best efficiency point. Therefore, the possibility of cavitation damage frequently becomes a consideration when selecting material for impellers.

Open-type mixed flow impellers that produce heads in excess of 35 ft (10.7 m) are particularly susceptible to cavitation erosion in the clearance space between the rotating vanes and the stationary housing. This is usually referred to as *vane tip erosion* and is caused by a cavitating vortex in the clearance space between the vane and the housing. It is also impractical in this instance to provide sufficient *NPSH* to eliminate the cavitation. Any evaluation of the impeller and housing for a pump of this type should include the possibility of vane tip erosion.

It was conventional wisdom in the pump industry until recent years that the cavitation resistance of a material was directly related to its hardness. A more sophisticated under-

standing has been developed in recent years that has led to the development of a new class of nonstandard stainless steels with exceptional cavitation resistance.

The relationship between cavitation resistance and hardness was first critically investigated in the 1970s when it was observed that cobalt base alloys of a modest hardness developed a very high resistance to cavitation damage. Cavitation resistance was related to the capability of the material to transform at the surface when subject to cavitation loading into a harder, more resistant metallurgical phase. This work was extended to austenitic stainless steels, whose chemical composition was adjusted to promote the formation of a stress-induced martensite under cavitation loading. New alloys were developed initially as weld filler metals to repair cavitation damage and later as impeller castings for pumps. These alloys have relatively low hardness in the solution-annealed condition, comparable to standard austenitic grades, but transform to a much harder martensite at the surface upon exposure to cavitation loading. The hard surface layer resists the initiation of fatigue cracks. If these cracks eventually develop after extended exposure to cavitation bubbles, propagation into the soft ductile base metal is difficult. Cavitation-resistant austenitic stainless steel castings, alloyed with chrome and manganese, develop cavitation resistance similar to that of cobalt base alloys.

Extensive laboratory tests of the resistance of a wide range of materials to cavitation erosion have produced data for all the materials commonly used in centrifugal pump construction. It is possible to make a good correlation between the laboratory data and field experience to develop the following tabulation of the cavitation-resistance properties of pump materials, listed in order of decreasing cavitation resistance:

- Stellite
- Chrome-manganese austenitic stainless
- Carburized 12% chrome stainless casting
- Titanium 6AL-4V
- Cast nickel-aluminum bronze
- Cast duplex stainless steel
- Cast precipitation hardening stainless steel
- Ductile NiResist
- Cast CF-8M
- Cast CA6-NM
- Cast CA-15
- Monel
- Manganese bronze
- Carbon steel (cast)
- Leaded bronze
- Cast iron

Selecting materials with adequate cavitation resistance will afford the pump designer much greater leeway in the range of conditions under which the pump can be operated. It also permits the design of smaller, lighter pumps that can be operated at higher speeds. The judicious use of materials significantly extends the time between outages caused by cavitation damage and can dramatically reduce maintenance costs.

TYPES OF WEAR

Rotating equipment, including pumps, can suffer from damage as a result of mechanisms unrelated to corrosion. The relative motion between parts that are in close proximity to each other can produce wear when these components come into contact with one another.

Catastrophic damage may occur if the parts make contact under high loading conditions or when foreign bodies are entrapped between the rotating and stationary components. An accelerated material loss or catastrophic seizure of these components can result in costly repairs or replacements. Erosion, due to the presence of solid particles in the liquid being pumped, can also limit the life of internal pump components.

Wear mechanisms have been categorized into more than 20 individual processes.¹ However, only a few mechanisms are frequently recognized as damaging to a pump:

- Adhesive wear: material-to-material contact
- Abrasive wear: solids interacting with internal components
- Erosion: solid particle impingement
- Fretting: small amplitude motion of parts causing oxidation damage

Identifying the wear mechanism is somewhat difficult at times as wear, or the loss of material, within a pump can result from more than one mechanism at a time.

The study of friction and wear as a science, known as *tribology*, had its beginning in the late 1930s. These early studies fostered an increased awareness of wear damage mechanisms that, in addition to corrosion and material fatigue, account for the life-limiting factors of pumps. Additional information on the study of wear can be found in current trade journals and texts.

Adhesive Wear One of the primary causes of material loss on rotating components in a pump handling clear liquids (with no solids entrained in the fluid stream) is adhesive wear. This material loss is due to material-to-material contact producing surface disruptions, material grooving, a transfer of material, and possibly galling. Two important characteristics to consider for a pair of materials that may come into contact are their adhesive wear traits and their galling threshold. Galling of a material is considered a severe case of adhesive wear.

The wear of two surfaces in relative motion is complex. Some alternative theories of sliding wear have been proposed in addition to the adhesive wear model. They are the delamination theory, the oxidation theory, the surface delamination theory, a fatigue model, and combinations of several of the theories mentioned. However, only the adhesive wear theory offers a general wear equation to quantitatively predict wear, thus providing a means to rank materials with respect to their wear characteristics.

A multitude of adhesive wear tests exist, including ring and block, pin and vee block, 4-ball, and pin on disk. Wear tests are performed in order to screen material combinations for potential usage. Therefore, wear tests are designed to simulate, as closely as possible, the actual service conditions and parameters.

The wear testing of materials under adhesive wear conditions has resulted in several generalities that are safeguards to the successful use of materials that may experience contact during service. Studies supported by EPRI, U.S. Naval research, and private industries result in lists of materials that are considered acceptable with regard to wear compatibility when contact does occur. From this testing, the material's hardness is determined to be the critical parameter for successful running combinations. The following guidelines should be used when selecting materials for services where adhesive wear is expected:

1. Like materials are not expected to run well under adhesive wear conditions (except for materials designed for antigalling resistance such as Nitronic 60 and Waukesha 88).
2. Combinations with hardness values less than $45 R_c$ require a hardness differential of at least $10 R_c$.
3. Combinations with hardness values greater than $45 R_c$ can have the same hardness.

Based upon extensive empirical testing and field experiences, several sound rules of thumb have been developed through the years when selecting pump wear ring materials. Three factors are used to select materials for wear surfaces in clear liquid environments:

- Corrosiveness of the fluid
- Amount of wear allowed
- Galling stress

Corrosion determines the class of material to be used. These classes generally fall into three groupings: non-corrosive, mildly corrosive, and corrosive. Of course, additional constraints occur when selecting an appropriate material within the corrosive material grouping that will need to be addressed by application experience.

Other material characteristics, such as additives, can significantly affect performance with regard to adhesive wear and galling. For example, copper alloys with lead additions are considered to be bearing alloys because of the capability of the lead to provide lubricity between contacting surfaces. Alternatives are being evaluated today to replace leaded bronze alloys to avoid the health considerations of lead usage. This is also true of tin and bismuth additions to nickel-based alloys.

A general guide for materials in several environments is as follows:

| Environment | Materials | Hardness |
|--------------------|--|--|
| Non-corrosive | Cast iron/leaded bronze | Unimportant |
| Mildly corrosive | Martensitic stainless steels (locally or through hardened) | Less than 45 R_c , 10-point differential Greater than 45 R_c , same hardness acceptable |
| Corrosive | Corrosion-resistant, non-galling austenitic stainless steel (Nitronic 50/Nitronic 60 or Waukesha 88/Nitronic 50) | Not applicable |
| Severely corrosive | Highly alloyed austenitic stainless steel with hard-faced materials such as Stellite or Colmonoy | Not applicable |

Using these industry-wide accepted rules of thumb will help avoid catastrophic damage normally resulting in costly repairs.

Some special applications have produced unique material applications for given environments. These include low specific gravity applications where the use of mechanical carbon materials is desirable because of the non-lubricating nature of these fluids. Common practice is to make the stationary component metal-filled graphite if the specific gravity is 0.5 or less. Stationary mechanical carbon components are also used in liquid CO_2 services and other potential dry start applications, such as the upper bearing in vertical pumps. Currently, non-metallic wear components, such as advanced polymers and ceramics, are being looked at to solve nagging problems encountered in a variety of applications. Usually, these are glass-filled polymers or ceramic composites with various additives to enhance their wear resistance.

Fretting Fretting can be considered a special case of adhesive wear. It occurs when two parts in contact experience a repeated, small amplitude relative motion between close-fitting surfaces such as a loose impeller on a shaft. Researchers have described fretting damage as a four-stage event:²

1. Adhesive wear of the asperities on the mating materials
2. Abrasive wear caused by the wear debris produced in step one
3. Abraded particles filling the asperity valleys
4. Elastic contact producing cold working of the surface and micro-pitting

In a pump, there is the potential for small amplitude motion at loose fitting impellers, beneath loose bearings, and between impeller wear rings and the impeller hub. The design engineer does not intentionally create a circumstance that will generate this type of motion, but when it occurs, fretting damage can lead to other problems.

Fretting can be identified by a red powdery oxide that forms along the fretted surface. In a pump, the red-colored debris is often washed away, but a distinct damaged surface appearance will develop on the fretted surfaces. This damage is often described as having a mottled appearance and is best depicted as a flat, eroded surface with no directionality to the damage. Although the oxide may be washed from the surface, some staining of the adjacent component can be observed after disassembly of the pump. This has led to the misinterpretation that fretting is a corrosion mechanism, but it is actually a special wear phenomenon.

Figure 8 shows the fretting damage of a pump shaft along the impeller-fitted area where a loose fit enables the oscillation of the impeller during operation. Since the motion necessary to cause fretting can be of a small amplitude, large vibrations in the pump may not be present. This makes the detection of fretting during any operation impossible. The impeller in this example would have similar damage along its bore.

Fretting damage can be avoided with a few relatively simple guidelines. You should eliminate or prevent the possibility of motion between the two components by either tighter clearances, or shrink fitting the assembly, which increases the clamping force. If fretting is unavoidable in a particular design, methods of mitigation can be used. These include various coatings or providing the contact zone with an appropriate lubricant. Coatings that may be used include flame-sprayed high-nickel alloys, silver plating, or possibly adding a thin, dense chrome plating to one or both of the faces in contact.

Abrasive Wear Abrasive wear is often categorized into two main classifications: *two-body* and *three-body wear*. The name indicates the mechanism of wear. For the most part, three-body abrasive wear is the primary mechanism of damage in centrifugal pumps. This can occur when hard solid particles entrained in the fluid enter between ring fit areas or impeller keyway faces. In fluids with high concentrations of solids, another form of three-

FIGURE 8 The fretting damage of a shaft beneath an impeller that experienced small amplitude motion. The mottled appearance is typical of the damage caused by fretting (2.2 \times).

FIGURE 9 Three possible conditions between wear surface clearances and solid particle size. Condition "A" is conducive to maximum three-body abrasive wear.

body wear is produced. Solids carried in the fluid stream can strike the internal pump surfaces. This is more commonly referred to as *erosion*. This type of damage is observed in the impeller and cutwaters of the casing. The degree of material damage, due to this mechanism, depends upon the bulk hardness of the material, the carbon content, and the characteristics of the solids present. Important particle characteristics include size, shape, hardness, and mass.

To minimize three-body abrasive wear, a couple of variables must be taken into consideration. The wear ring clearance influences damage. The relationship between the size of the particles in the fluid stream and the gap into which they can enter is important. This is graphically illustrated in Figure 9, which shows three types of particle-to-gap relationships. Condition A is logically the most damaging three-body abrasive case. A high rate of damage will result as these particles are entrapped between the two components. In condition B, large particles relative to the ring clearance will not enter and produce damage. This condition enables the particles to flow with the fluid stream through the eye of the impeller and exit the pump. In condition C, very fine or relatively small particles will not be entrapped and ground between the rings and will not result in collateral damage of the components.

For the most part, particles in a fluid service will be in a range of sizes, so all the conditions will exist. Typically, a particle size and distribution analysis is performed to characterize the amount of particles that will cause condition A to exist. This is relatively simple to accomplish by extracting the solids from a fluid sample and performing a sieve analysis. The percentage of solids present in the fluid stream is extremely important for determining the appropriate material and design considerations. This will be addressed later with guidelines given for appropriate material selections.

Wear particle hardness is also extremely important. If particles are soft and friable, such as talc, little damage would be expected to occur on metal pump components because of three-body abrasive wear. The amount of damage is expected to be greater if the particles are extremely hard. These particles include welding scale or silicon dioxide (SiO_2), which is sand. The particle geometry also contributes to the amount of damage that can result in three-body abrasive wear. Often, particles of SiO_2 are found in a rounded condition. Pumps used to handle river water or seawater on ships frequently encounter these configurations. Hard, round particles are less damaging than particles of equal hardness with sharp, angular configurations. Fly ash, a very hard, sharp, angular particle, is one of the most abrasive services encountered in the pump industry.

A material's resistance to abrasive wear can be characterized by a standard ASTM test procedure. Each testing procedure attempts to simulate the mechanism that most appropriately addresses the class of abrasive wear. In general, materials that are resistant to two-body abrasive wear are resistant to three-body abrasive wear also.

Test results show that the primary property responsible for increasing resistance to abrasive wear is the hardness of a metal alloy. Zum Gahr has provided test results to graphically illustrate this fact.³ Small microstructural differences, alloying, and surface-condition differences within alloy groups also can influence the abrasion resistance of a material. Some of these conclusions include the following:

- Abrasion resistance is increased with increasing bulk material hardness.
- At the same bulk hardness, steels with higher carbon content have higher abrasion resistance.
- Cold working, which increases a material's surface hardness, does not significantly increase the abrasion resistance of the alloy.
- Precipitation hardening increases the bulk material hardness and abrasion resistance of an alloy.
- Gray cast irons show a decreasing abrasion resistance at higher hardnesses.
- Softer, austenitic, white cast irons exhibit improved abrasion resistance over martensitic, white cast irons.
- Carbides are important for the wear resistance of steels and chromium-alloyed, white cast irons.
- A carbide volume fraction of 30% maximizes the abrasive wear resistance for materials with a soft matrix.

An example of three-body abrasive wear is shown in Figure 10. It shows a laser-hardened shaft sleeve after approximately one year of service in a mine dewatering operation where abrasive wear caused a significant wear of other material combinations. The abrasive wear was caused by fine tailings in this gold mine application. To increase the life of rings in services like this, the use of hardened wear rings is a good start. This is the reason why pump producers use coated rings in applications where significant abrasive wear is anticipated. However, depending upon the severity of the service, a choice of a ring material containing carbides may be necessary.

For mildly abrasive services, the following materials should be considered:

- Ni-Resist—Its resistance is due to chromium carbides in the matrix. It has good adhesive wear resistance also.
- Selectively hardening the surface of AISI 420 (laser hardened 50–55 R_c). Surface hardening is not susceptible to hydrogen embrittlement or SCC.
- Carburized and hardened 12% chromium stainless steel.

For more abrasive services, the following is often considered:

- Hardened AISI-440C (50–55 R_c)
- Stellite or colmonoy-coated (hard-faced) austenitic stainless steel
- Solid stellite
- Tungsten carbide
- Silicon carbide
- Partially stabilized zirconia (PSZ)

Recent advances involving the use of ceramics, metal-matrix composite materials, laser-surface alloying, and laser-surface modifications to a substrate that normally could not survive in an abrasive service are examples of ongoing material developments.

FIGURE 10 The three-body abrasive wear of a laser-hardened shaft sleeve in an abrasive service. Note the fine concentric scoring of the hardened surface. The helix pattern is the laser-beam overlapped zone produced by the laser process.

Erosion Most fluids handled by pumps are considered clear liquids, meaning they do not have significant amounts of solid particulates present. The corrosive nature of these fluids dictates the required pump materials. Guidelines for many of these services are embodied in “Corrosion in Pumps,” a tutorial published in the Ninth International Pump Users Symposium.⁴

However, many fluid-handling applications requiring pumps are far from clear liquids. Solid particulates can be removed with costly filtration systems that must work flawlessly at all times. Fabricated piping systems may introduce suspended solids from weld slag and pipe burn. Naturally occurring suspended solids are those found in water sources such as river water or seawater, as mentioned previously in the abrasive wear section.

The following factors should be considered during the material and pump selection phase of the procurement process:

- The hardness of the particles
- The quantity of particles
- Size distribution
- Nature (geometry)
- The velocity of the pumpage
- The angle of fluid impingement

The first four items listed deal with the suspended solids. These variables can vary from application to application. The hardness of the particles is important to understand in determining the materials necessary to yield an acceptable pump lifespan. Hardness can range from relatively soft substances, such as cellulose fiber in pulp and paper applications, to very hard abrasive particles such as silicon or rock in mining pumps. The Miller

number index, as described in ASTM G75,⁵ is used to characterize the abrasivity of hard particles.

The Miller number was developed to determine the relative abrasivity and attrition of solid particles making up a slurry. In a closed loop test, the abrasivity of the particles becomes less damaging with time due to the fracturing and rounding (or friability) of the particles as they strike each other and/or impinge on a pump or casing wall.

The Miller number is therefore reported with two numbers. The first number characterizes the abrasivity of the particles and the second is the loss of abrasivity (attrition) of the particles during the slurry test. The abrasivity portion of the Miller number is useful in practical applications because this more closely characterizes a slurry's damaging potential. The attrition number has found little use other than characterizing a test loop's influence on a slurry. A slurry with a Miller number less than 50 is not considered abrasive in a reciprocating pump. Examples of slurries with a Miller number below 50 are limestone, sulfur, and detergent. It has been determined that a slurry consisting of finer particles is less abrasive than one containing larger particles. Test data shows that Corundum at 220 mesh is about four times as abrasive as the same material at 400 mesh.⁵

Particle velocity plays a major role in the degree of damage that occurs in a pump handling slurries. In this case, the potential energy is converted into kinetic energy, producing a material loss by the transfer of energy from the particle to the component. The amount of material damage on an individual particle scale depends specifically upon particle velocity, v , and mass, m (kinetic energy, defined as mv^2). This is demonstrated by Finnie's equation⁶ for hard materials:

$$\text{Wear rate} = (\# \text{ of impinging particles}) \times (\text{average particle mass}) \\ \times (\text{impingement velocity})^2 \times (\text{angle of impingement})$$

Of course, the pump part that absorbs the kinetic energy resulting from the particle impact has a role to play also. The material hardness and/or resilience of the pump component in absorbing the particle's impact energy will also determine the amount of material loss.

Chen and Hu⁷ have performed laboratory tests on materials while changing the particle variables previously described. Their test results show the following:

- An increased particle hardness increases the material loss up to 1700-kg/mm² micro-hardness (greater than 75 R_c). Beyond this hardness, a decrease in wear occurs. This is most likely the result of the hard, brittle particle fracturing, which absorbs some of the kinetic energy.
- Sharp, angular particles increase the erosion rate over round particles.
- Erosion increases with increasing concentrations of abrasive particles.
- An increased fluid (and particle) velocity increases the erosion rate.
- Minimal erosion occurs at an impingement angle of 0° (tangent to the target surface) and increases to a maximum amount of wear at a 65° angle.

A review of the literature shows that several authors have plotted the solid particle impingement angle versus the amount of erosion.^{8,9} These plots show that for ductile materials, erosion increases with the increasing impingement angle to a maximum material loss at an angle of 25°. Then the erosion damage decreases to the 65° impingement angle previously mentioned. Brittle materials, such as glass, are quite different. As the impingement angle increases from 0° to 90°, the volume of material loss continuously increases.

The characteristic features of erosion damage due to solid particle impingement are usually recognizable. However, when an aggressive fluid is present, the effects of solid particle impingement may not be easily identified. These effects can appear very much like corrosion-erosion, which is a fluid velocity-controlled damage mechanism where entrained solids are not present. If this damage is misdiagnosed, an improper material substitution can be made that may not solve the real problem. Conversely, a more likely situation is

FIGURE 11 The severe erosion of a carbon steel casing in a 17% bauxite and sand service. Note the gouging due to the local turbulence of the slurry.

FIGURE 12 Erosion at the exit vane tips of a duplex, stainless steel CD4MCu impeller in a bauxite service.

FIGURE 13 An austenitic stainless steel impeller in an abrasive fly ash service that shows severe erosion. Increased erosion occurs with an increasing fluid velocity near the periphery of the impeller.

FIGURE 14 Erosion damage of an AISI-type, 440C stainless steel ball valve in a coal slurry service

that the observed damage resulting from the erosion-corrosion is misinterpreted as solid particle erosion. A full understanding of the pumpage including the fluid velocity, fluid corrosiveness, content, and nature of the solid particles present is necessary for the appropriate action to be taken in improving the life of a damaged pump.

An example of solid particle erosion in a pump is shown in Figures 11 and 12. The severe erosion damage of a casing is illustrated by the gouging of surfaces that were directly impinged or scoured by glancing blows of the solid particles in the fluid stream. This pump handles a bauxite slurry where the percentage and velocity of alumina (Al_2O_3) and sand are too high for the carbon steel casing and CD4MCu impeller.

Figure 13 shows a CF3M impeller in a fly ash service. This shows that the greatest damage to the impeller is at the outer periphery, which corresponds to the highest velocity of the slurry. The least amount of damage is near the impeller inlet eye. Figure 13 also shows that the lower velocity region of the impeller inlet eye has the least damage. This confirms the laboratory data that shows an increased erosion with an increased slurry velocity. Note that the damage increases near the outside of the inlet eye and is almost nonexistent at the impeller hub where the fluid velocities are lower.

Erosion damage can also be encountered in reciprocating pumps. Figure 14 shows extensive erosion of an AISI-type, 440C stainless steel ball from a ball valve after it

became stuck and unable to rotate in a coal slurry application. This caused a slurry impingement on a concentrated region of the ball.

The particle velocity and impingement angle are design factors that can be used to mitigate erosion in pumps. The challenge in the coal liquefaction program investigated by the Department of Energy in the 1970s was to develop a high-speed pump for handling coal-oil slurries.⁸ This was attempted because traditional slurry pumps are usually large, slow-moving machines that increased the capital and operating costs of pilot plants built during that era. Most of the slurry pump industry utilizes large, slow-moving, single-stage pumps to address the solid particle erosion problem. Many of these pumps are rubber-lined to absorb the particle's impingement energy.

Erosion damage, once identified, has a limited number of solutions to prolong the longevity of pump materials. This can be accomplished by the selection of hard, wear-resistant replaceable liners, elastomeric liners, or, in cases where liners cannot be utilized, hard materials. Such metallic materials include white cast iron (such as Ni-Hard), high chromium (13 to 28 percent) alloy steels, cobalt-based super alloys (such as Stellite), and nickel-based alloys.

FATIGUE

Centrifugal and reciprocating pumps are subjected to cyclical loading, which, if not considered during design, will result in a limited life due to material fatigue. In combination with a corrosive environment, material fatigue can be accelerated due to what is commonly referred to as *environmentally assisted fatigue*.

The one essential parameter in component fatigue is the presence of an alternating or cyclic load. In general, pumps are machines that have either fluid or mechanically induced cyclic loading on their components. Although centrifugal pumps are for the most part steady-state rotational equipment, pulsations or fluctuating applied stresses are encountered. The source of these cyclic stresses can be from fluid interaction between impeller exit vanes and diffuser vanes or, in a volute pump, the impeller vanes and the casing cut-water. Mechanically induced forces are due to bending moments acting on the pump shaft or possibly a component imbalance in the rotor assembly. Reciprocating pumps experience a cyclic loading of the internal and external components from the action of the machinery. In fact, these pumps can be thought of as large fatigue-testing machines due to the pulsating action of the pumping process.

When cyclic forces are applied to materials in a pump over a period of time, a crack may initiate at the component's surface. After initiation, the crack will grow with continued cyclic loading until the part finally fractures. Fractures can occur, even though the loading produces stresses that are far less than the tensile strength of the material. Engineers have been aware of this potential mode of component fracture for many years and have developed design criteria that take this anomaly into account. The study of cyclic loading and material behavior based upon cyclic stress history and flaw size is beyond the scope of this text. It should be noted, however, that the field of fracture mechanics offers an engineering design tool that can predict the life of an engineered component.

Fatigue is a three-stage process consisting of (1) crack initiation, sometimes associated with preexisting defects, (2) crack propagation, and (3) the final fracture, associated with crack instability, as suggested by Wohler.¹⁰ The applied stress level, sample geometry, flaw size, and mechanical properties determine the existence and extent of these stages.

Fatigue was first studied by August Wohler in 1852.¹¹ Wohler's work included the concept of alternating applied stress, S , and the number of cycles, N , applied to a sample until a fracture occurs. This work is the basis for today's S/N curves used by design engineers. A laboratory-generated S/N curve is shown in Figure 15. This curve was generated by smooth, rotating-beam test specimens. These specimens are machined carefully to avoid metallurgical notches on their surfaces that would lower the applied stresses required to produce a failure during testing.

When a corrosive media is introduced, many crack initiation sites are produced. The lower curve shows the resulting drop in the endurance limit. Since corrosion over time can

FIGURE 15 A laboratory-generated S/N curve for a smooth bar rotating beam test specimen

TABLE 2 Corrosion fatigue strength of alloys in sea water*

| Alloy | UTS | CFS |
|---------------------|-----|-----|
| Ti-6Al-4V | 154 | 88 |
| Inconel 718 | 189 | 60 |
| Inconel 625 | 149 | 50 |
| Hastelloy C | 108 | 32 |
| Monel alloy K-500 | 176 | 26 |
| Ni Al bronze (cast) | 115 | 15 |
| 304 Stainless | 79 | 15 |
| 316 Stainless | 85 | 14 |
| 304L Stainless | 75 | 14 |
| 316L Stainless | 79 | 13 |
| 17-4PH - cast | | 10 |
| 70-30 Cu-Ni (cast) | 83 | 9 |
| Ni Mn Bronze | 82 | 9 |
| Mn Bronze | 73 | 8 |
| D-2 Ni-Resist | | 7.5 |
| Mild steel | | 2 |

*Test parameters: ambient temperature, 1750 rpm, 2–3 ft/s (0.6–0.9 m/s). Corrosion fatigue strength (CFS) given at 100,000,000 cycles. All values are in ksi; 1 ksi = 6.894759 mPa. (UTS is ultimate tensile strength of material in air.)

increasingly damage the material, the endurance limit will correspondingly decrease with the exposure time. No true fatigue limit exists for materials in a corrosive environment. For this reason, the corrosion-assisted fatigue life of a material is usually published with cautionary statements. Given enough time, corrosion can penetrate completely through a fatigue test specimen, resulting in a data point of zero load and zero cycles. For this reason, corrosion-influenced fatigue test results usually specify the corrosive media, the test temperature, the details of the sample pre-exposure to the corrosive media, and the test frequency with respect to the applied cyclic loading.

Published data varies because laboratories that use a low frequency of applied stresses increase the influence that corrosion has upon the test specimens. This is in comparison to laboratories that conduct these tests at a high frequency that minimizes the influence of the corrosive media. Published values for the ultimate tensile strength and corrosion fatigue strength of various alloys are shown in Table 2.¹²

Wohler's investigation shows that a mechanical notch can reduce a material's fatigue.¹⁰ This is shown in Figure 16 as a shift in the S/N curve below the curve produced by a smooth bar specimen. The severity of the notch determines the amount of divergence from the smooth bar curve. As shown, the surface degradation mechanisms lower the stress

FIGURE 16 A shift in the S/N curve below the curve produced by a smooth bar specimen. The severity of the notch determines the amount of divergence from the smooth bar curve.

FIGURE 17 SEM photo of a fracture smooth fatigue test specimen with a single origin. The arrow indicates the fatigue crack origin.

FIGURE 18 Multiple origin fatigue fracture of a pump shaft. The arrows show the locations of the many fatigue crack origins. A and B correspond to the final fracture zone of each fracture face.

needed to produce the specimen failure after a certain number of cycles. This in turn reflects a lowering of the material's endurance limit.

The three stages of fatigue cracking can be observed on the fracture face, rendering them easily identifiable. This is especially true if no other secondary damage masks the characteristic appearance. Especially in fractures that occur over long periods, lines are visible on the fracture surface. These bands are sometimes referred to as *clamshell markings*, *crack arrest lines*, or *beach marks* and reflect different periods of crack growth. Ratchet lines, which represent the joining of two different crack fronts on different planes into one, are observed in multiple origin fatigue cracks. Multiple origin fatigue fractures are often associated with rotating components.

Figure 17 shows a high magnified view of a smooth bar fatigue specimen after a fracture. The arrow shows a single origin of this specimen. This fatigue crack propagated across the entire specimen diameter until the final fracture occurred, shown as a small circle. The final fracture is sometimes referred to as the *ductile overload zone* or the *fast fracture zone*.

An example of a fatigue fracture on a pump shaft is shown in Figure 18. The arrows in this figure indicate the location of many crack origins. The flat, smooth surface appearance

of this fracture face is characteristic of most fatigue fractures. This flat fracture appearance is sometimes mistaken for a brittle fracture because no evidence of plastic deformation is observed on or near the break. Shown almost directly in the center of the fractured shaft section is a small area of ductile overload, marked A and B, which corresponds to the final fracture area. The relatively small size of this area indicates the crack propagated under low alternating loads. In other words, the only material holding the two halves of the shaft together was the last area to fracture. This is a mere fraction of the total cross-sectional area of this shaft. The multiple arrows at the OD of the shaft shows the many crack origins. Fatigue ratchet marks are at each of these locations. This type of fatigue fracture is referred to as *multiple origin, high cycle fatigue*.

As mentioned before, an investigator uses the relative size of each fatigue crack stage to determine the magnitude of the loads acting on the component. The identification of the crack origin is also of prime concern in conducting a failure analysis. The crack origin is important to determine if the fatigue crack initiated from a flaw in the material or a notch produced in service or during manufacturing.

Corrosion, often the primary cause of pump material damage, can increase the likelihood of fatigue cracking. *Corrosion-assisted fatigue* is the name given to this special type of cracking. Corrosion damage can change the surface texture and significantly increase the local stresses acting on the pump component. If the corrosion damage is severe enough to produce a sharp notch in a region of high cyclic loading, then fatigue cracking of the component is inevitable. In some cases, the propagation phase is also influenced by oxidation, which can mask the telltale features of the fatigue mechanism. Corrosion oxides, which form along the crack face, can produce a wedging effect, which mechanically increases the local tensile forces acting on the crack tip. This increases the crack propagation rate.

An example of corrosion-assisted fatigue at two locations in the front shroud wall of an impeller is shown in Figures 19 and 20. The evidence of corrosion pitting on the surface indicates a strong possibility that corrosion influenced the fracture mode. Further investigation shows that both shroud wall fatigue fractures were initiated at corrosion pits located in highly stressed areas of the impeller. The fluid pulsations acting on the exit vane tip result in alternating loading.

Corrosion is not the only mechanism of surface degradation that can promote this form of cracking. Surface disruptions through fretting or wear can also provide sites for fatigue crack initiation. Sharp radii and defects at the material surface such as porosity and poor machining act as stress concentrations.

Once the mechanism of fatigue cracking has been identified, suitable corrective actions can be implemented. These include the following:

FIGURE 19 Overall view of a CF-3M impeller that has two corrosion-fatigue fractures in the front shroud wall

FIGURE 20 A higher magnification of one of the fatigue fractures that originated at a corrosion pit at the exit vane tip and shroud intersection. Additional corrosion pitting can be seen on the impeller in this figure.

- **Higher strength materials** A good approximation for the endurance limit of a metal is 50% of the material's tensile strength. This is for high-cycle fatigue where no macro plastic loading is experienced. A graph published in *Deformation & Fracture of Engineering Materials*¹⁰ shows this rule of thumb.
- **Design modification** The stress acting upon a component can be reduced with an increased section size. Reducing the stress on a component will increase its life. The design criteria for mean stress in an alternating loading environment can be determined using several analytical models. Since components are subjected to a range of loading (not a constant amplitude), a fluctuating mean stress is encountered. The anticipated load history can aid in the design process to avoid fatigue fractures. The prediction of potential component life can be based upon a fluctuating mean stress design criterion, referred to as the *Pamgren-Miner cumulative damage law*.¹⁰
- **Surface treatments** The introduction of compressive stresses to the surface of a part increases the fatigue life of a component. This is usually performed at crack-sensitive regions such as sharp corners or notches. If compressive stresses are introduced into the surface of a material, cyclic tensile stresses in excess of the compressive stress value are needed to cancel their effect before fatigue damage can occur. Therefore, any form of compressive stress will benefit a component with respect to fatigue cracking. Compressive stresses can be introduced by (1) cold working, (2) shot peening, or (3) a local heat treatment that introduces beneficial, compressive residual stresses (such as laser hardening or induction hardening).
- **Increased corrosion-resistant materials** The use of more highly corrosion-resistant materials is beneficial in cases where corrosion has decreased a component's life by degradation of its surface condition.

MATERIALS OF CONSTRUCTION

Impellers The pump designer needs to consider several criteria when selecting the material for the impeller:

- Corrosion resistance
- Abrasive wear resistance
- Cavitation resistance
- Casting and machining properties
- Weldability (for repair)
- Cost

For many water and other noncorrosive services, bronze satisfies these criteria and, as a result, is the most widely used impeller material for these services. Bronze impellers should not be used for pumping temperatures in excess of 250°F (120°C). This is a limitation imposed primarily because of the differential rate of expansion between the bronze impeller and the steel shaft. Above 250°F (120°C), the differential rate of expansion between bronze and steel will produce an unacceptable clearance between the impeller and the shaft. The result will be a loose impeller on the shaft.

Leaded bronzes have been used extensively in the past as impellers, especially in less demanding applications. The lead addition to bronze enhances its castability and machinability. In recent years, environmental concerns associated with lead have caused many nonferrous foundries to stop producing these alloys and pump manufacturers are increasing their use of unleaded bronzes for impeller applications.

It should be noted that bronzes have velocity limitations above which they will suffer accelerated erosion corrosion. The maximum velocity, which will correspond with the periphery of the impeller, is higher in fresh water than in salt water. The most resistant bronzes, able to tolerate the highest velocities, are the nickel aluminum bronzes. These

alloys are often used as impellers in salt water applications because they combine high mechanical properties, good corrosion resistance, and the capability to be weld-repaired. A nickel aluminum bronze impeller can be designed for a higher speed than any other bronze impeller alloy.

Cast-iron impellers are used to a limited extent in small, low-cost pumps. Cast iron is inferior to bronze in corrosion, erosion, and cavitation resistance. It also cannot be welded to repair damage due to wear or erosion. For these reasons, a low initial cost is usually the only justification for selecting a cast-iron impeller.

Martensitic stainless steel impellers are widely used where bronze will not satisfy the requirements for corrosion, erosion, or cavitation resistance. The alloys most commonly used are CA-15 and CA-6NM. These alloys can be used for pumping temperatures above 250°F (120°C), as the differential expansion problem no longer exists with a steel impeller on a steel shaft. Martensitic stainless steel impellers are used in a wide range of applications, including boiler feed water, many cooling waters, and a variety of hydrocarbon applications. It does not have sufficient resistance to pitting corrosion for use in sea water.

Martensitic stainless steels are heat-treatable alloys. The specified mechanical properties are developed through a quench and temper heat treatment. Quenching can be in oil or, as is more common, in air. The cooling rate in air is sufficiently rapid that the high temperature austenitic structure will transform to the metastable martensitic structure, which can subsequently be tempered to the desired hardness. The designer should specify that tempering be done at a minimum temperature of 1100°F (600°C) in order to assure that the casting has adequate toughness. It is also important that these alloys be heat-treated after weld repairs. This can present a problem in the case of a finish machined casting, which would suffer distortion if heat-treated. Welding techniques have been developed, however, that do not require a post-weld heat treatment, but these are, in most cases, unsuitable for use on martensitic stainless impellers.

Oil and refining industry applications often involve exposure to hydrogen sulfide, which may be present as a trace contaminant in hydrocarbon fluids. Martensitic stainless steels are susceptible to a form of SCC in this environment and should be specified with a special double-temper heat treatment designed to limit hardness and thereby prevent cracking.

Austenitic stainless steels are used for impellers in applications requiring a higher level of corrosion resistance than can be obtained from the martensitic grades. A number of different alloys make up this group. The most widely used are CF-8M and CF-3M, which are the cast versions of the well-known 316 and 316L wrought materials. The cast alloys have a slightly different chemistry than the wrought grades. This difference accounts for the presence of 5 to 15% ferrite in the castings, which makes them slightly magnetic. The ferrite also enhances the resistance to SCC and hot shortness, a casting problem associated with fully austenitic cast grades. These alloys provide corrosion resistance over a wide range of pH and have reasonably good resistance to pitting and crevice corrosion in aqueous chlorides.

Higher alloyed austenitic cast grades are also available for applications requiring a greater degree of corrosion resistance. Alloy 20 contains about 30% nickel and was developed for sulfuric acid applications. The high nickel makes the alloy fully austenitic (without ferrite). Consequently, it is difficult to cast and suffers from hot shortness, which may manifest itself as fine cracking at the intersection between the vane and the shroud in an impeller. The high nickel content also makes Alloy 20 very resistant to SCC.

Austenitic grades containing 6% molybdenum have been developed for use in salt water and other high-chloride applications such as acidic brines used in oil field waterflood injection. The high level of molybdenum makes these alloys fully resistant to pitting in stagnant seawater, which will be present when a pump is not in operation. The 6% molybdenum grades are more expensive and therefore not frequently used for most applications. These alloys are usually considered only for critical, demanding applications where a high level of corrosion resistance is needed.

Austenitic stainless steels with unique properties have been developed for specific applications. A chrome-manganese alloy, discussed in the section on cavitation erosion, can be employed to mitigate or entirely eliminate cavitation damage in problem applications.

A high-strength austenitic stainless grade, CF10SMnN, can be used where the mechanical properties of CF-8M are inadequate. Some pump manufacturers also offer nitrogen-enriched austenitic grades that have corrosion resistance and mechanical properties better than CF-8M.

Duplex stainless steels offer a combination of higher mechanical properties and better corrosion resistance than the standard austenitic grades. The original duplex casting grade, CD4MCu, was developed in the 1950s. Use of this material was limited by problems with castability and weldability. Improved steelmaking technologies now enable the addition of precise amounts of nitrogen to duplex stainless steel. The nitrogen addition improves castability, weldability, and also corrosion resistance. Numerous duplex stainless grades have been developed in recent years, all having a specified nitrogen addition. These duplex grades all outperform the old CD4MCu grade, which did not have a nitrogen addition. Many foundries now make CD4MCu with nitrogen.

Duplex stainless impellers are extensively used in mining, flue gas desulfurization, and similar applications that require a combination of resistance to corrosion and abrasion. Duplex stainless steels also have better corrosion resistance than the standard austenitic grades and are used in a variety of applications in the chemical industry, the pulp and paper industry, and the marine industry. Duplex stainless pumps are standard for offshore high-pressure water injection pumps in the oil industry. Published corrosion data indicates that, for acceptable resistance to seawater, a duplex stainless should contain a minimum of 25% chrome, 3% molybdenum, and 0.15% nitrogen.

Casings The following criteria should be considered when selecting material for centrifugal pump casings:

- Strength
- Corrosion resistance
- Abrasive-wear resistance
- Casting and machining properties
- Weldability (for repair)
- Cost

For many pumping applications, cast iron is the preferred material for pump casings when evaluated on the basis of cost. For single-stage pumps, cast iron usually has sufficient strength for the pressures developed. For corrosive or hazardous petroleum products, it may be necessary to specify cast steel or cast stainless steel. The concern with cast iron when handling hazardous fluids is that the material is inherently brittle and could fail suddenly in a catastrophic manner with no prior indication of distress.

Cast-iron casings for multistage pumps are limited to approximately 1000 lb/in² (6.9 MPa) discharge pressure and 350°F (177°C). For temperatures above 350°F (177°C) and pressures up to 2000 lb/in² (13.8 MPa) discharge pressure, a cast steel is usually specified for split-case, multi-stage pumps. For pressures higher than 2000 lb/in² (13.8 MPa), a cast or forged steel barrel-type casing is usually required.

In any evaluation of cast iron versus steel casings, consideration should be given to the problem of casing erosion during operation. Erosion can occur either from abrasive particles in the fluid or from wire drawing across the flange of a split-case pump. Although the initial cost of a steel casing is higher than that of a cast-iron casing, a steel casing can often be salvaged by welding the eroded portions and remachining. Salvaging a cast-iron casing by welding is much more difficult, and the casting usually must be replaced.

The ductile irons are useful casing materials for pressure and temperature ratings between cast irons and steels. Although the modulus of elasticity for the ductile irons is essentially the same as that for cast iron, the tensile strength of the former is approximately double that of the latter. In any evaluation of the ductile irons as a substitute for the steels in the intermediate pressure and temperature range, it should be remembered that ductile iron casings cannot be effectively repair-welded.

Austenitic irons, commonly known by the tradename *Ni-Resist*, are used for pump casings in applications where gray and ductile irons have insufficient corrosion resistance. Austenitic irons typically contain 15 to 20% nickel. They are frequently used in brackish and salt water applications where they are considerably more resistant to both corrosion and erosion than unalloyed gray iron. A preferred combination for this service is a Ni-Resist casing and stainless internals. The stainless steel is galvanically protected from pitting when the pump is made idle by the more anodic Ni-Resist casing.

The traditional Ni-Resist alloys have poor weldability in common with other types of cast iron. In recent years, a new and more readily weldable Ni-Resist grade has been developed. This grade, designated *D2W*, contains a small columbium addition that enhances weldability. This new D2W grade is gaining popularity as the preferred grade for pump casings.

Bronzes are also used for pump casings in many water applications. Several bronzes are used, with the choice depending upon the specific application. Leaded bronzes, specifically leaded red brass, are used for small low-pressure pumps. This material is the least costly and easiest to cast of the bronzes. Tin bronzes, with or without lead, are used for larger centrifugal pump casings. The lead contributes to the pressure tightness of the casting. Unleaded bronzes often have to be impregnated in order to obtain adequate pressure tightness. Unleaded tin bronze can be weld-repaired, whereas the leaded version is not weldable. Nickel aluminum bronze has the highest mechanical properties and the best corrosion resistance of the bronze alloys normally considered for pump casings. It can also be repaired by welding. Nickel aluminum bronze casings are expensive and usually not competitive on a cost basis with NiResist or other alternatives.

Stainless steels are selected for pump casings when required due to corrosion considerations. Martensitic stainless steels are commonly used to handle boiler feed waters as well as many hydrocarbon applications. These materials have good mechanical properties and are suited for high-pressure applications. Their corrosion resistance is less than that of other categories of stainless steel and for this reason, they are unsuited for more aggressive waters or other fluids.

The austenitic stainless steels, particularly CF-8M and CF-3M, are frequently used for pump casings in chemical applications and other corrosive services. These materials can handle a wide range of pH. They are resistant to erosions by high velocity and can be field-weld-repaired with relative ease.

Duplex stainless steels (stainless steels having a metallurgical structure that is approximately 50 percent ferrite and 50 percent austenite) are used for pump casings in some applications that require a combination of corrosion resistance and mechanical properties superior to that of the standard austenitic grades. These materials have become the preferred choice for high-pressure, offshore injection pumps handling sea water. The higher mechanical properties permit the design of thinner wall, lighter pumps. The weight savings is an important factor in this application.

Shafts The following criteria should be considered in the selection of material for a centrifugal pump shaft:

- Endurance limit
- Corrosion resistance
- Notch sensitivity

The endurance limit is the stress below which the shaft will withstand an infinite number of stress reversals without failure. Since one stress reversal occurs for each revolution of the shaft, this means that ideally the shaft will never fail if the maximum bending stress in the shaft is less than the endurance limit of the shaft material.

In practice, however, the endurance limit is substantially reduced because of corrosion and stress raisers, such as threads, keyways, and shoulders on the shaft. In selecting the shaft material, consideration must be given to the corrosion resistance of the material being pumped as well as to its notch sensitivity. Corrosion will substantially lower the fatigue limit of the material. Fatigue cracks will initiate at corrosion pits or other surface discontinuities that act as stress risers.

In the absence of corrosion, an approximate relationship exist between fatigue endurance limits and mechanical properties. The endurance limit is equal to roughly half the tensile strength of the material. Depending upon the application, the pump designer will usually select the least expensive shaft material that will satisfy the three criteria noted previously. Carbon steel is used when corrosion resistance is not required, and relative low mechanical properties can be tolerated. A low alloy steel, often AISI 4140, is used when the mechanical properties of carbon steel are not adequate. Martensitic stainless steels, usually type 410, are a common choice when some measure of corrosion resistance, combined with reasonably good mechanical properties, is required. The resistance of type 410 stainless to fatigue crack initiation is related to the toughness of the material, which can vary over a wide range in commercial bar stock. The best measure of material toughness is the Charpy impact test, which is not a requirement of most relevant material specifications. In order to ensure the optimum toughness and resistance to fatigue cracking, type 410 stainless should be tempered at a temperature of 1100°F (593°C) minimum.

Stainless steels offering improved corrosion resistance and mechanical properties are also used in pump shafting. These include Nitronic 50, an austenitic grade, and 17-4PH, a precipitation hardening grade.

Several manufacturing issues related to the creation of pump shafts also need to be considered. Difficulty has frequently been experienced when maintaining the stringent tolerances for straightness required for long, thin shafts that are used in multi-stage pumps. This may necessitate intermediate stress relief during the machining process. The shaft may be stress-relieved in the vertical position or, if horizontal, with supports every few feet. Type 410 pump shafting can be specially heat-treated to eliminate residual stress and maintain straightness tolerances during pump operation.

Shafts can be plated or coated in specific areas for an improved resistance to wear or corrosion. Chrome plating is commonly used in this manner. The designer needs to be aware that plating reduces the fatigue endurance limit because of the fine micro-cracking associated with this process. An improvement in fatigue life can be achieved on plated surfaces if the substrate is shot peened. Normally, this reduction in endurance limits is not critical, because it is the flat surfaces, rather than the shoulders or keyways, that are being plated. Consequently, the largest stress raisers are elsewhere in the shaft. There is also the potential for the plating process to cause hydrogen embrittlement cracks in high-strength steels. To avoid this problem, the steel should be baked at 300 to 400°F (150 to 200°C) after the plating process.

Finally, the manufacturing process needs to be carefully controlled to avoid the inadvertent introduction of stress raisers, which could shorten the life of the shaft. Abusive grinding has been identified as the root cause of some shaft fatigue failures. Heavy grinding will heat the surface and cause hardenable steels to form a thin layer of untempered martensite. This is a brittle structure and likely to develop fine cracks. These are stress raisers that can be propagated by a fatigue mechanism once the pump is placed in service. This type of problem is avoided by proper controls on the manufacturing process.

Wear Rings The following criteria should be considered in the selection of the material for the wear rings:

- Corrosion resistance
- Abrasive wear resistance
- Galling characteristics
- Casting and machining properties
- Suitability for coating

A centrifugal pump will often have both case and impeller wear rings. The impeller wear ring rotates within the bore of the stationary or case wear ring. These rings provide a close running clearance to minimize leakage from the discharge to the suction of the impeller. As the rings wear with use, leakage will gradually increase, affecting the head, capacity, and efficiency of the pump. In multistage (flexible rotor) pumps, increased wear ring clearance may also affect rotor stiffness.

To reduce the rate of wear of the wear rings, and thereby increase the life of the pump, special considerations must be given to the corrosion and abrasive wear characteristics of the ring material. Since the impeller and case rings may occasionally touch one another, the combination should also be selected to have anti-galling characteristics.

Bronze is a widely used material for wear rings because it exhibits good corrosion resistance for a wide range of water services. In addition, bronze exhibits good wear characteristics in clear liquids but tends to wear rapidly when abrasive particles are present. The bronzes also have a relatively good resistance to galling. The leaded bronzes offer excellent galling resistance but use of these grades has been reduced due to environmental concerns associated with lead. The casting and machining properties of most grades of bronze are excellent.

In applications where bronze is not suitable because of either corrosion or abrasive wear limitations, or where pumping temperatures exceed 250°F (120°C), stainless steel rings are used. Unlike bronze, the stainless steels of the 300 and 400 series have poor galling resistance. Several options are available to minimize the possibility of galling between stainless steel rings. The clearance between the rings can be increased, serrations can be machined into one of the rings, or a minimum hardness differential of 50 to 100 Brinell points can be established between the rings, if made from a hardenable grade of stainless, such as the martensitic grades. If both rings are hardened to above 400 BHN, it is not necessary to maintain a hardness differential.

Martensitic stainless steel rings are usually hardened in a furnace. A laser hardening process is also available that involves heating only the surface of the material, which is rapidly quenched by the base metal, resulting in a precisely controlled surface hardness and a soft ductile core. Rings hardened in this manner are more resistant to cracking in some environments and provide increased wear resistance because of increased surface hardness (50-55 R_c). A summary of adhesive wear test results can be found in Table 3.

Increasing the clearance between rings is the least costly method for reducing the risk of galling or seizures. However, increasing the clearance will reduce the output and efficiency of the pump. In large, low-head pumps, the loss in efficiency is less than one percent, but in small, high-head pumps, the loss in efficiency can be significant. Serrated rings

TABLE 3 Calculated wear factor

| Material (Ring/Block) | Hardness DPH (Ring/Block) | Wear Factor K |
|---|---------------------------|-----------------------|
| In Distilled Water Specific Gravity 1.0 | | |
| Leaded Bronze/ASTM A48 Class 30 CI | 80/205 | 0.17×10^{-4} |
| Ni-Resist/Ni-Resist | 120/120 | 0.41×10^{-4} |
| Nitronic 50/Nitronic 60 | 195/190 | 0.76×10^{-4} |
| 90-10 CuNi/ASTM A48 Class 30 | 87/210 | 1.14×10^{-4} |
| Stellite 12/Stellite 6 | 440/395 | 1.71×10^{-4} |
| Ampco 18/Ampco 18 | 155/155 | 2.40×10^{-4} |
| AISI 410/ASTM A743-CA6NM | 300/270 | 2.45×10^{-4} |
| AISI 410/AISI 416 | 290/430 | 2.97×10^{-4} |
| AISI 416/AISI 416 | 430/360 | 3.57×10^{-4} |
| In Alcohol Specific Gravity 0.87 | | |
| Nitronic 50/Nitronic 60 | 195/190 | 0.62×10^{-4} |
| Leaded Bronze/ASTM A48 Class 30 | 80/205 | 1.54×10^{-4} |
| AISI 410/AISI 416 | 290/430 | 7.38×10^{-4} |
| In Iso-octane Specific Gravity 0.69 | | |
| Leaded Bronze/ASTM A48 Class 30 CI | 80/205 | 0.41×10^{-4} |
| Nitronic 50/Nitronic 60 | 195/190 | 0.69×10^{-4} |

can be used on smaller pumps to help maintain the efficiency level, but only at an increase in manufacturing costs.

For cast-iron, bronze, hardened 11- to 13% chromium steels, and materials with similar low-galling tendencies, the recommended minimum running clearances between rings are given in API Standard 610, "Centrifugal Pumps for Petroleum, Heavy Duty Chemical, and Gas Industry Services." For materials with higher galling tendencies, such as austenitic stainless steels and for all materials operating at temperatures above 500°F (260°C), it is suggested that 0.005 in (0.125 mm) be added to the recommended minimum diametrical clearances.

Several anti-galling material combinations have been used that do not compromise either wear or corrosion resistance. Nitronic 60 is a nonstandard austenitic grade that contains both manganese and nitrogen. This alloy has been developed for antigalling characteristics and will resist galling when mated with standard 300-series grades, Nitronic 50, and other alloys having poor galling resistance. Nitronic 60 is available in both wrought and cast forms. A cast nickel base alloy, Waukesha 88, offers equally good antigalling characteristics and can be used in brine and other corrosive environments. A summary of galling thresholds for commonly used material combinations is shown in Tables 4 and 5.

Colmonoy- or Stellite-coated rings are used in some critical applications and provide a high degree of resistance to abrasive wear, corrosion, and galling. These coatings are applied by welding, which can produce unacceptable distortion in rings, especially in larger diameters. The pump designer needs to exercise caution in specifying rings having a weld overlay because of potential manufacturing problems, which can involve cracking of the weld overlay or distortion of the ring. Some large rings for sewage pumps have performed well with tungsten carbide coatings applied using a high-velocity plasma spray process. The advantage of this process is that it does not heat the substrate, thereby avoiding distortion. Tungsten carbide is used for its high hardness and resistance to abrasion.

SELECTION OF MATERIALS OF CONSTRUCTION

The selection of materials for pumps is often not a simple and straightforward matter because of the weight assigned to various technical and economic factors by different

users. A final selection may involve a compromise between the manufacturing cost and the anticipated maintenance costs. This is particularly true for fluids like sea water, for which a wide range of materials have been used, from cast iron pumps with bronze internals to 6% molybdenum austenitic stainless steels. Despite the fact that economic factors unique to a particular application may influence the choice of materials for that application, some general guidelines can be used for some of the more common fluids.

Boiler Feed Water/Condensate High purity water at a high temperature can be very corrosive to cast iron and carbon steel despite the fact that it usually has a low oxygen content. These materials will suffer erosion corrosion, sometimes within months, if incorrectly applied. High purity water is defined as that having a conductivity of 20 micromhos/cm or less, which is equal to a dissolved solids content of 10 ppm or less. At these low levels, carbon steel and cast iron are incapable of developing surface films such as magnetite that minimize erosion corrosion. The precise mechanism is not well defined, but the relationships between conductivity, oxygen content, pH, temperature, and the influence of these variables on erosion corrosion were established by pioneering work conducted at the Detroit Edison Power Plants in the 1950s.

The purity of feedwaters has increased over the years as water treatments have become more effective in removing dissolved solids to meet the demands of modern boilers. As a consequence, these waters have also become more corrosive. The early work at Detroit Edison showed that chromium additions to carbon steel dramatically enhance the resistance to erosion corrosion in high purity water. Chrome additions of 1–1.25% are sufficient in most boiler feedwaters to impart acceptable corrosion resistance. Pump manufacturers initially used 5% chromium alloy steels for these applications. Difficulties in casting and welding five-percent chromium steels led to the more recent use of 12–13% chrome steels, notably CA-15 and CA-6NM. These are now commonly used in boiler feed pumps, condensate pumps, and others that handle high purity waters.

Water purity is often reported in the fluid's conductivity. Units of micromhos or microsiemens are used for this purpose. It has been determined that for high-temperature, boiler feed water services greater than 200°F (greater than 93°C), care in selecting materials is important for ultra pure waters. For waters greater than 200°F (93°C) with a conductivity less than 20 μ mho and alloys with greater than 3% chrome, an addition is required to avoid corrosion erosion at high-velocity areas. Figure 21 shows a carbon steel shaft that was severely damaged in ultra pure water. The proper selection of materials can be achieved by using Figure 22 as a guideline.

Some applications still remain in which cast iron, bronze, and other less costly materials can be used. Materials are selected based on water chemistry, which is divided specifically into four parameters: pH, temperature, conductivity, and dissolved oxygen. Table 6

FIGURE 21 The corrosion erosion of a carbon steel shaft that was damaged in an ultra-pure water service after approximately six months

FIGURE 22 A graph indicating the proper materials selection in specific pH ranges for boiler feed services

NM—1- or 2-chrome barrels—12% chrome impeller (CA-15 or CA-6NM)

S—All 316 stainless (CF-3M)

represents an industry consensus on the recommended materials choices for the full range of high purity waters.

Saline Water Saline waters have been defined as those that are sufficiently electrically conductive to enable an appropriate pump casing material to galvanically protect the pump internals when the pump is shut down. This corresponds to waters with more than

about 1000 ppm chloride. Many pump applications involve saline waters. Among the more common saline water applications are the following:

- **Tidal river water** The chloride level here can fluctuate significantly with the season and the ingress of salt water from a bay or estuary.
- **Groundwater** The chloride level and corrosivity can vary over a wide range. Some groundwaters, which are injected by high-pressure pumps into oil formations to enhance output, are very corrosive, due to low pH and very high chloride levels.
- **Geothermal water** This type may contain high levels of hydrogen sulfide, carbon dioxide, and other gases in addition to chlorides.
- **Oilfield brines** These are often deaerated, greatly reducing their corrosivity. Less corrosion-resistant pump materials may be used but are susceptible to corrosion during shutdown periods when oxygen cannot be effectively excluded from the water.
- **Sea water** The chemical composition of seawater is relatively uniform throughout the world. Other factors, including temperature, microbiological activity, and the presence of pollutants can alter the corrosivity of the seawater to pump materials of construction.

For each of the saline waters, a variety of materials has been used for pumps. The choice of materials for a particular application will depend on the water chemistry and other factors including the expected life of the pump, whether it will operate continuously or sit idle for long periods, and user preferences based on previous experiences. Some general considerations will influence material selections.

The materials for saline water pumps must resist erosion corrosion. Ni-Resist and copper base alloys are frequently specified but have velocity limits, above which the protective oxide film is stripped off and accelerated corrosion occurs. Among copper base alloys, nickel aluminum bronze can tolerate the highest velocity. The pump designer needs to be aware of these limitations and use bronze and Ni-Resist only for components when the velocity limits of the materials will not be exceeded.

Stainless steels develop a more tenacious oxide film than bronzes and can tolerate velocities much higher than those seen in pumps without suffering erosion corrosion. However, stainless steels are susceptible to pitting and crevice corrosion in stagnant seawater. These problems are exacerbated if marine biofouling occurs. Several methods exist for handling this problem. The stainless internals of a pump can be effectively protected by galvanic coupling with Ni-Resist. The combination of a Ni-Resist case and stainless steel internals is widely used because of this favorable galvanic relationship.

To avoid localized corrosion during shutdown in an all-stainless pump, some form of cathodic protection is required. This can be either sacrificial anodes or an impressed current system. It is also possible to construct the pump of stainless grades that are highly alloyed and develop adequate corrosion resistance. This approach requires either 6% molybdenum austenitic grades or 25%, 3% molybdenum duplex grades. These materials are considerably more expensive than standard 300-series austenitic stainlesses and see limited use in critical applications. Higher alloyed duplex grades have become the universal standard for high-pressure injection pumps, especially those used in offshore locations. The high mechanical properties enable the design of lighter, smaller pumps. The weight saving is an important factor in offshore applications.

Many large sea water pumps are constructed of cast iron with bronze internals. Provided the velocities are not too high, this combination of materials has been known to provide approximately 20 years of service in some large vertical pumps. Nickel aluminum bronze is preferred over tin bronze for the impeller because it is stronger, has better resistance to high velocity, and is more easily weld-repaired.

Monel shafting is no longer commonly specified for sea water pumping applications. This material is expensive and will develop pitting in stagnant water. Several grades of stainless steel will provide a combination of strength and corrosion resistance equivalent to Monel at a significantly lower cost. These include Nitronic 50 and several of the higher alloyed duplex grades, such as Ferralium.

When specifying materials for sea water pumps, the designer should also consider whether the water will be chlorinated, and, if so, where the chlorine is to be added. Chlorine is added to cooling waters to kill marine organisms that cause biofouling. The chlorine may be added continuously at low levels or as a shock treatment at periodic intervals. Chlorination at normal levels of up to 2 ppm does not appear to be detrimental to alloys commonly used in saline water pumps. However, an injection should be made far enough upstream of the pump intake so that the dilution occurs ahead of the pump. When an injection is made at or near the pump intake, copper alloys, stainless steels, and Ni-Resist may suffer accelerated corrosion. Recent work has shown that the corrosion rate of stainless steels will begin to increase at chlorine levels of about 5 ppm.

Galvanic considerations will also play a role in the material selection for saline water pumps. In general, the pump internals should be cathodic to the pump case. Coatings should be avoided, especially on the anodic component. Flaws or defects in a coating will expose a small area of base metal. Corrosion will then proceed at a high rate due to the extremely unfavorable area ratio. It is also inadvisable to use carbon or graphite bearings in sea water pumps. These are at the noble end of the galvanic series and are likely to cause a galvanic corrosion of stainless steels or other alloys with which they come in contact.

Table 7 indicates a number of material combinations commonly specified for seawater pumps.

Hydrocarbons Pure hydrocarbons are not corrosive, but they frequently contain small amounts of water or other substances that make them corrosive. The material selection guidelines for a variety of hydrocarbon services have been developed by the American Petroleum Institute and are reproduced in Tables 8 and 9. These tables give general guide-

TABLE 7 Materials for saline water pumps

| | Component | Reference | Alternative | Non-ferrous |
|---|-------------|--|---|---------------------------------|
| Vertical Pumps | Column/Head | Ni-Resist ¹ | 316L | C614 ⁴ |

1. The materials for pump parts for each material class are given in Table 9.

2. Separate materials recommendations should be obtained for services not clearly identified by the service descriptions listed in this table.

3. Cast iron casings, where recommended for chemical services, are for nonhazardous locations only. Steel casings (S-1 or I-1) should be used for pumps in services located near process plants or in any location where released vapor from a failure could create a hazardous situation or where pumps could be subjected to hydraulic shock, for example, in loading services.

4. Mechanical seal materials: For streams containing chlorides, all springs and other metal parts should be Alloy 20 or better. Buna-N and Neoprene should not be used in any service containing aromatics. Viton should be used in services containing aromatics above 200°F (95°C).

5. Oxygen content and buffering of water should be considered in the section of material.

6. The corrosiveness of foul waters, hydrocarbons over 450°F (230°C), acids and acid sludges may vary widely. A materials recommendation should be obtained for each service. The material class previously indicated will be satisfactory for many of these services but must be verified.

7. If production corrosivity is low, Class S-4 materials may be used for services at 451–700°F (231–370°C). A separate materials recommendation should be obtained in each instance.

8. All welds shall be stress relieved.

9. Alloy 20 or Monel pump material and double mechanical seals should be used with a pressurized seal oil system.

10. For seawater service, the purchaser and the vendor should agree on the construction materials that best suit the intended use.

11. Class A-7 materials should be used, except for carbon steel casings.

The abbreviation above the diagonal line indicates the case material; the abbreviation below the diagonal line indicates trim material.

Abbreviations are as follows: BRZ = bronze, STEL = steel, 12% CHR = 12% chrome, AUS = austenitic stainless steel, CI = cast iron, 316 AUS = Type 316 austenitic stainless steel.

Parts designated as *full compliance* materials shall meet all the requirements of the industry specification listed for the material. Parts not designated as *full compliance* materials shall be made of materials with applicable chemical composition but need not meet the other requirements of the listed industry specification.

¹Austenitic stainless steels include ISO Types 683-13-10/19 (AISI Standard Types 302, 303, 304, 316, and 347). If a particular type is desired, the purchaser will so state.

²For vertically suspended pumps with shafts exposed to liquid and running in bushings, the shaft shall be 12 percent chrome, except for Classes S-9, A-7, A-8, and D-1. Cantilever (Type VS5, API 610) pumps may utilize AISI 4140 where the service liquid will allow.

³Unless otherwise specified, the need for hard-facing and the specific hard-facing material for each application shall be determined by the vendor and described in the proposal. Alternatives to hard-facing may include opening running clearances or the use of non-galling materials, such as Nitronic 60 and Waukesha 88, depending on the corrosiveness of the pumped liquid.

⁴For Class S-6, the shaft shall be 12 percent chrome if the temperature exceeds 350°F (175°C) or if used for boiler feed service (refer to Table 8).

⁵The gland shall be furnished with a non-sparking floating throttle bushing of a material such as carbon graphite or glass-filled PTFE. Unless otherwise specified, the throttle bushing shall be premium carbon graphite.

⁶If pumps with axially split casings are furnished, a sheet gasket suitable for the service is acceptable. Spiral-wound gaskets should contain a filler material suitable for the service.

⁷Alternate materials may be substituted for liquid temperatures greater than 110°F (45°C) or for other special services.

⁸Unless otherwise specified, APSI 4140 steel may be used for non-wetted case and gland studs.

lines that do not necessarily apply to every situation. In many hydrocarbons, hydrogen sulfide is present as a contaminant.

Hydrogen sulfide causes a form of stress corrosion cracking in hardenable steels and other alloys. Additional precautions must be taken when hydrogen sulfide is present, consisting of special heat treatments to limit hardness. Details concerning the requirements for specific materials can be found in NACE standard MR-01-75.

Naphthenic acid is an organic acid that is found in many crude oils. It causes corrosion problems at temperatures in excess of 450°F (232°C). Austenitic stainless steels containing molybdenum, either 316 or 317, are required for effective resistance against naphthenic acids.

Amine solutions have caused cracking in welded carbon steel components that have not been post-weld heat treated. Although repairs to carbon steel casings may not require post-weld heat treatment, it is prudent to specify this for welds made to rotating components or piping welds to a casing.

MATERIALS FOR SLURRY AND ABRASIVE SERVICES

The construction materials for pumps that handle high concentrations of suspended solids are often based upon high bulk hardness. In many applications, coatings, hard liners, and weld overlays are used to specifically increase the surface hardness of the internal wetted portions within the pump. However, many of the slurry applications use non-metallics that do not have high bulk hardness because of their unique qualities.

Nonmetallics Contrary to “harder is better,” a good number of slurry pumps use non-metallic materials, such as rubber, that absorb the kinetic energy of the solid particles through a large elastic deformation of the surface. Natural rubber is the most commonly used material since it provides good wear resistance with abrasive particles less than approximately 0.25 to 0.38 in (6 to 9 mm). Rubber linings pose a problem in the bonding of this outer shell to a metallic substrate. This is particularly true for cut water areas of a casing and, of course, attachment to metal skeletons of an impeller. Care must be taken also in considering the liquid phase of the slurry and the temperature of the application, both of which can degrade the rubber.

Other factors to consider when using elastomeric liners include pressure in the flow passage versus the pressure between the liner and the wall, and temperature, since rubber softens around 240°F (115°C). It is also important to consider the size of the particles greater than 0.2 in (5 mm) if they are dull or greater than 0.08 in (2 mm) if they are sharp, and the head per stage.

Metals In mildly abrasive services, carburized steels are sometimes used to increase the wear life of components. Carbon is diffused into the surface of carbon steel, which, after a hardening heat treatment, can achieve a surface hardness of 60 R_c . This gas diffusion heat treatment can produce high hardness layers that penetrate the outside surface of the pump component to a depth of approximately 0.080 to 0.090 in (2.0 to 2.3 mm). However, after carburization, the materials are impossible to weld-repair without cracking. Using a special process, usually a vacuum furnace, carburizing has been employed in the surface hardening of the 12% chromium stainless steels, such as CA15, for abrasive services where mild corrosion is expected.

The most commonly used materials for severe slurry services are the abrasion-resistant cast irons found in ASTM A532. Essentially, three main classes and several types of alloys are covered in this specification. The most widely employed material in slurry applications is the Class III hard irons. A brief description of this class of abrasion-resistant iron is as follows:

| ASTM A532 Grade | Composition (Cr, Ni, and Mo) | Hardness (BHN) |
|--|------------------------------|---|
| Class I: Type A (Ni-Hard) | 1–11% Cr, 3–7% Ni | 500–600 |
| Class II: Type A, B, C, D, E | 11–23% Cr, 0.5–3.5% Mo | 450 (annealed for machining) 600 (hardened) |
| Class III: Type A (26% chrome iron, original trade name of HC-250) | 23–28% Cr | 400–600 depending on desired properties |

All three classes contain a martensitic matrix with secondary hard phases of chrome and iron carbides that increase the wear resistance. The molybdenum in class II increases the material's hardenability for thicker cross sections.

In general, it should be stressed that machining and welding these three classes of material is impossible. Another important consideration is the role of carbon content on corrosion, erosion, and fracture resistance. High-carbon contents reduce corrosion resistance because any chromium tied up as chrome carbide is no longer available to form a protective chrome oxide layer. Although beneficial with regard to erosion and abrasion resistance, high-carbon content increases the susceptibility to breakage by thermal and mechanical shocks.

To counteract this problem, a number of precautionary measures must be adopted to enhance the serviceability of this class of material. First, slow warm-up cycles must be instituted, typically around 100 to 150°F per hour.¹⁴ Another strategy is to lower the hardness from about 600 to 400 Brinell by a partial anneal. This measure reduces brittleness, but at the expense of erosion resistance.

Linings, Inserts, and Coatings The low ductility and toughness of A532 cast irons do not permit their usage with primary pressure boundaries according to ASME code and API regulations. This restricts the use of hard irons to internal wetted parts. Therefore, it is necessary to use steel pressure casings with hard materials as liners. A common slurry pump consists of ASTM A532, Class III, Type A (HC-250) impellers and replaceable HC-250 wear liners for the volute and for both the inlet and outlet ends of the pump casing.

Since pump erosion is often quite localized, in some instances it is more practical to install replaceable, mechanically attached inserts at high wear areas, such as the cut water. These are typically made of sintered tungsten carbide or some other hard material. Newer materials, such as ceramic composites and toughened ceramics, should perform better than the “cermets” used in the past.

Several problems, however, can occur with mechanically attached inserts. One problem is protecting the fastening device against erosive wear. Another problem is the insert's tendency to act as a turbulence riser due to an imperfect fit or erosion-induced crevices and offsets. Limited success has been achieved with weld-applied overlays of Stellite and other hardfacing materials. Weld overlays are extensively utilized, but several problems may occur. These include a propensity for cracking, debonding resulting from preferential corrosion of the bond line, dilution of the hardfacing material with the substrate, and potential uneven thickness after machining.

Thermal spray coatings as well as diffusion surface treatments have been used in pump applications for fluids containing high concentrations of suspended solids. Spray coatings are restricted to areas within the pump, accessible by the line of sight. Diffusion-produced coatings are not limited by this constraint. A disadvantage of diffusion processes is that they are performed at high temperatures that can negatively influence the base material properties. Diffusion coatings can range from traditional gas carburizing to the diffusion of high chromium alloys. These coatings increase the sur-

face hardness of the component and, depending upon the process, can increase the material's surface hardness to values in excess of $60 R_c$. Diffusion layers can be produced to a depth of approximately 0.100 in (2.54 mm). One item of caution: these coatings usually render the material unweldable after application. For this reason, steps must be taken to protect areas of anticipated welding, such as attachment piping. Future weld repairs are not possible unless the coating is completely worn off or removed.

Through the years, developments in thermal spray equipment have enhanced the acceptability of this surface modification process. Thermal spray processes employ the transfer of a material onto another by raising the temperature of the hard-facing material, usually in powder form, and projecting it against the component that requires the additional erosion resistance. The bond strength between the hard-faced material and the substrate material is directly influenced by the maximum velocity that the particles of molten material achieve in a given thermal spray process. The greatest bond strength is achieved by the highest velocity process. The typical thermally sprayed materials used in pumps to resist solid particle erosion damage are as follows:

- Nickel chromium boride coatings
- Cobalt-based hardfacing coatings
- Tungsten carbide coatings
- Solid particle tungsten carbide loaded (1) or (2)

The processes used to apply the above hardfacing materials are as follows:¹⁵

| Process | Typical Particle Velocity |
|--|---------------------------|
| Flame spray | 100 ft/s (30.5 m/s) |
| Plasma spray | 800 ft/s (244 m/s) |
| D-Gun (Union Carbide tradename for detonation gun process) | 800 ft/s (244 m/s) |
| HVOF (high velocity oxy-fuel) | 3000 ft/s (915 m/s) |

The severity of the service usually dictates the process. In the past, thermal spray coatings, for the most part, were tungsten carbide and the diffusion coatings were high in borides. It was found that for spray coatings an increased performance could be achieved by applying them over erosion-resistant substrates. This is a challenge because the high-chromium, carbon, abrasion-resistant materials are thermal-crack-sensitive. Overlay coatings, if applied several times, are thicker but are more prone to cracking, chipping, and spalling. An alternative is to use carburized carbon steel or 12% chromium stainless steel centrifugal pump components for mildly corrosive environments. Coatings are frequently used to increase the life of plungers in reciprocating pumps for slurry services.

Another process for applying hard-faced materials is by laser consolidation. This process can be accomplished in two different ways. The first case is one in which a laser beam is used to melt a thermally sprayed coating applied upon a substrate. The other process is to simultaneously melt the substrate while applying a hard-faced material. In either case, the principle is to use the hard-faced material as a consumable in a laser-welding operation. Since laser welding is a rapid process, very little dilution of the hard facing material is produced. This allows for much thinner coatings that are less prone to thermally induced cracking during an operation. In addition, since there is little dilution, the hardness and chemistry of the coating are very consistent. This provides for uniform erosion resistance throughout the entire coating thickness.

SUMMARY

It should be clear from the discussion of materials for saline waters and hydrocarbon applications that the selection of materials for a pump is a complicated exercise, requiring knowledge of the engineering properties of the material, its fabrication characteristics, and corrosion and erosion resistances. An in-depth discussion of the considerations governing material selections for other pump applications, such as the chemical industry, mining industry, and others, is beyond the scope of this section, but a number of references are included to provide additional guidance. Past experience is often helpful, but it is recommended that the materials selections be reviewed by a metallurgist or corrosion engineer with experience in this area, especially for critical applications or those applications with which you are not familiar.

SECTION 5.2

MATERIALS OF CONSTRUCTION FOR NONMETALLIC (COMPOSITE) PUMPS

FREDERIC W. BUSE

The use of composite materials is playing an increasing role in the manufacture of industrial pumps due to the cost savings they offer in manufacturing, installation, and operation. Composite parts can be molded to near “net shape.” This eliminates the cost of secondary machining to attain the final part. Because one composite material can replace two or three different grades of metal part, the combining of several parts into one assembly is possible. This parts integration reduces assembly time, reduces inventory, and ultimately reduces manufacturing costs.

Because composite pumps weigh less than metal pumps, they are easier to handle during installation and maintenance. Further, because composites naturally dampen vibration, a composite pump operates more quietly than a comparable metallic pump.

The corrosion resistance of composites is superior to metals. For this reason, a composite pump’s life can be significantly greater than a metallic pump. When the amortization costs of both composite and metallic pumps are calculated, the composite pump has the cost advantage.

FACTORS TO CONSIDER

Factors to consider in using composite materials for pump parts are mechanical properties, abrasion and corrosion resistance, temperature, costs, weight and insulating properties, exposure to sun, fire resistance, and chemical resistance.

Mechanical Properties The composite pump or parts must be designed to withstand the loads/stresses of the operating conditions. If the existing metal part design were simply replicated in a composite, the composite part could fail. Excessive stresses for a composite pump at the nozzle area or at the bearing housing can cause the pump housing to creep. The result is part distortion or bending and shaft misalignment.

A solution to this problem is to calculate the stress levels in the composite part and design within the composite's elastic limit. These complex stress calculations are now done on a routine basis with the aid of a computer and non-linear FEA (finite element analysis) programs.

Abrasion and Corrosion Resistance The abrasive wear on 316 stainless steel is caused by the continuing removal of the metal's protective oxidation layer on the metal's surface. Composites do not need a protective layer and therefore have better resistance to mild abrasives. However, some composites are subject to corrosion by caustic liquids.

As background, metallic materials deteriorate from any one or combination of the following electrochemical reactions: galvanic action, pitting, corrosive attack, crevice corrosion, intergranular corrosion, and stress corrosion. The temperature, pH, formation, removal of an oxide corrosion barrier, or the velocity of the solution affects the rate of corrosion in a metal's surface.

Temperature Most composite pump materials are limited to operating temperatures below 300°F (150°C) for non-corrosive liquids and under 250°F (120°C) for corrosive liquids. Like metals, there is a reduction of mechanical properties for composites with increasing temperature.

Costs There are three areas of cost to consider when evaluating a composite part: development costs, initial capital costs, and cost savings.

Developing costs would include the following:

- Designing the part for composites
- Evaluating and testing alternative composite materials
- Prototype molding the parts

Initial capital costs are in the cost of the molds to produce the parts. Cost savings in manufacture and use include the following:

- Little or no corrosion increases the time between maintenance and extends the useful life of the pump.
- Reduced secondary machining cost at manufacture (the parts are near "net shape")
- Integrating several parts into one assembly results in a less expensive part, lower inventories, and less assembly time.
- Quality control cost is reduced as part tolerance is primarily determined by the mold.

The initial cost of a composite pump versus a metallic pump is typically as follows:

- equal or slightly more expensive than an all 316 stainless steel pump
- 80% the cost of an Alloy 20 pump
- 50% the cost of a Hastelloy C pump

Weight and Insulation Properties With a significant reduction in weight compared to metal, the composite pump is easier to handle during installation and maintenance removal. As an example, an immersion sump pump that is usually 3–10 ft long weighs only 10–30% of a comparable metal pump.

Added insulation on the pump to conserve high temperature process heat is usually not needed on a composite pump, as the composite is a natural insulator when compared to metal. This saves the cost to fabricate an insulation cover over the pump and provides easier access for maintenance.

Exposure to the Sun Some composites are susceptible to the UV (ultraviolet) rays of the sun. 2% carbon black in the resin is an effective UV blocker. HALS (hindered amine

light stabilizers) can also be added to the composite to effectively prevent damage by the UV rays of the sun.

Fire Resistance In a severe fire, thermoplastic composites will melt and burn and thermoset composites will char and ash. If the composite reaches 400–500°F (204–260°C), there will be distortion of the pump and the pump will be lost. Because of the insulating properties of a composite pump housing, however, the liquids inside the pump will be cooler than if the pump were metal.

Fire retardant additives can be used with composite materials, but they may affect optimum mechanical properties. Most thermoset composites are self-extinguishing in a fire, but the pump manufacturer should be consulted to determine if there is a potential for toxic fumes if the composite is burned.

CHEMICAL RESISTANCE OF COMPOSITES

Composites do not corrode because they are non-conductive. Therefore, an electrochemical reaction does not take place. (An exception to this may be when electrically conductive long carbon fibers are used in the wrapping of a pressure vessel or a pump housing.) Their lack of resistance to different chemical fluids can degrade composite materials. This degrading can be in the resin, the reinforcing fiber, or in the coupling agent between the resin and fiber. If a composite material is going to be degraded, it will usually be immediate. Fluid temperature and concentrations are vital when selecting the appropriate composite material. With some composites, such as nylon, the pH can be a factor when selecting the best composite material for the application.

As an initial test, a sample coupon of the composite can be immersed in the process liquid and the results noted. A more definitive method is to review the composite manufacturer's informational database on chemical resistance. Many composite manufacturers have run extensive chemical resistance studies of their materials in a variety of liquids at set temperatures over time. The composite's physical properties are measured before and after the test period and the percentage deterioration versus time is documented in the manufacturer's literature.

The Hydraulic Institute, discussed later, has a polymer material selection guide that recommends specific composites for various liquids.

TYPES OF COMPOSITES

Composites can be divided into two general groups of organic compounds: thermoplastic and thermoset.

Thermoplastic Thermoplastic materials can be repeatedly melted and solidified. They do not go through an irreversible chemical process when heated. Amorphous thermoplastics resins have a broad softening range and are suitable for processes that require good melting strength like thermoforming. They can be transparent in color but do have limited chemical resistance.

Crystalline thermoplastic resins have a sharp melt point and are better suited to molding processes like injection molding where melt strength is not required. They have excellent chemical resistance. Their physical properties can be modified and improved with the addition of glass or carbon fiber, tougheners, or mica. Chart 1 shows the effect of various reinforcement materials on selected polymers.

Some of the thermoplastic processes that are used to form pump parts are injection molding, vacuum forming, extrusion, and blow molding. Thermoplastic resins suitable for pump applications include fluoropolymers, acrylics, polyethylene, polypropylene, polyvinyl chloride, and others. The allowable temperature range for these materials is from

CHART 1 Thermoplastics strength versus reinforcement

FIGURE 1 The effect of temperature on modules of elasticity

130–300°F (54–150°C), depending on the material. Figure 1 shows the elastic modulus versus service temperature for various polymers.

Thermoset Thermoset materials, when heated, go through an irreversible chemical change with the result that the material will not soften when reheated. Thermoset resins are generally reinforced with glass fiber, linen, carbon fiber, graphite, minerals and so on.

TABLE 1 Differences between Thermoset and Thermoplastic

| Process | Thermoset | Thermoplastic |
|-----------------------------------|---------------------------------------|---|
| Average range of molded thickness | .030 to 2.00 in (0.75 to 50 mm) | .06 to .50 in (1.5 to 13 mm) |
| Weight range of piece | 1 to 500 lb (0.5 to 225 kg) | 0.5 to 5.0 lb (0.22 to 2.26 kg) |
| Glass content by volume | 50 to 60% | 30 to 40% |
| Length of glass fiber | 0.25 in (6 mm) to several inches (mm) | 0.06 in (1.5 mm) |
| Strength | Not uniform throughout | Uniform |
| Minimum annual quantities | Less than 1000 | 10,000 |
| Obtain strength from ribs | Not necessarily | Yes |
| Tooling | Depends on complexity and size | Generally 20 to 30% higher than compression molding |
| Process | Compression or resin transfer | Injection, cannot use compression molding. |

They have an allowable application temperature range of 180–250°F (82–120°C), depending on the material. Examples of thermosets are epoxies and vinyl esters. They can be stronger than thermoplastics but are usually more brittle. Thermosets are processed by comparison molding or transfer molding. They have good chemical resistance to acids, bases, and oxidizing agents.

Table 1 outlines the differences between thermoset and thermoplastic polymers.

LINED PUMPS

To provide chemical resistance for a metallic pump, it is possible to install a flexible, rigid, or sprayed-on liner inside the pump housing. With a flexible lined pump, a metal casing is made to the design shape and pressure. Then a loose liner is fitted inside the pump housing and bonded to the metal casing with an adhesive. This type of liner can come loose under vacuum conditions. There also can be problems at the termination of the liner to the mating pipe flanges.

A resin used in some lined pumps is PTFE (polytetrafluoroethylene). By itself, PTFE does not have the physical properties needed for a pump housing. When it is supported by a metal housing, however, it provides an excellent lining material due to its outstanding range of chemical resistance at high temperatures.

Rigid pump liners are machined out of plastic stock shapes or molded into a near net shape. The liner is then mechanically compressed between bolted steel plates to provide the support. Such pumps are usually small in size.

A sprayed-on composite lining is made by taking a metal casing of the required pressure rating, heating it, and then spraying the composite material inside the housing and flanges. At 0.030 in (0.76 mm) thickness, the lining will not have pinholes and is suitable for pump applications. This lining process is usually limited to pumps that require up to 100 horsepower (75 kW) drives.

Table 2 gives an overview of the comparative advantages and disadvantages of the different styles of pumps.

CERAMIC AND CARBON PUMPS

Solid ceramic or carbon pumps are used for very hostile liquids such as concentrated hydrofluoric acid. Ceramic and carbon pumps are much more expensive than non-metallic pump materials, but do have the chemical resistance required for extremely aggressive chemicals.

TECHNIQUES FOR MOLDING PUMP COMPONENTS

Injection molding is a process for high volume forming of high quality thermoplastic parts. The part cost is low, but the initial mold costs can be high. The reinforcing materials for injection molding are short strand fibers (0.06 to 0.50 in or 1.5 to 13 mm long) and are glass, graphite, mica, and so on.

Compression or transfer molding uses thermoset resins and can make small quantities of larger parts. The mold costs are less, but the part price is usually more due to trimming and secondary machining steps. The reinforcing materials for these processes can be continuous or chopped mat strands, as well as woven mats and blankets. These long strand fibers give exceptional physical properties to the final part.

MECHANICAL PROPERTIES OF COMPOSITES

Composites in general have far lower physical properties when compared to steel and lower physical properties than aluminum or brass. Composites can, however, be designed to withstand the operating pressures of a pump by increasing the section modulus of the part; that is, increasing the wall thickness. Table 3 shows some unreinforced composite properties versus steel. Figure 2 illustrates where the various composites and metallic are positioned and applied on a grid of developed pressure versus flow.

Thermoplastics PVC and CPVC pumps are low-cost and suitable for the lower temperature ranges. PVC can be used up to 140°F (60°C) and CPVC, with greater abrasion resistance, is suitable for temperatures up to 210°F (100°C). PVC and CPVC can be solvent-bonded together to attain the best attributes of each resin in a single pump.

Polypropylene (PP) has excellent corrosion resistance and is used in hydrocarbon service up to 185°F (85°C). It is not suitable for strong acids or chlorinated hydrocarbons. The material can be ultrasonic, vibration, and spin welded in assembly.

PVDF (Kynar) is very corrosion- and abrasive-resistant and suitable for temperatures up to 300°F (150°C). It is also relatively expensive.

PTFE (Teflon) is extremely corrosion resistant, but its low physical properties require it to have a metal reinforcement backing to withstand high pump pressures. Table 4 is a partial list of thermoplastics used for pump parts.

Thermosets Vinyl esters and epoxies are the strongest of the thermoset composites and usually do not require external metal reinforcement. Vinyl esters are resistant to corrosion, whereas the epoxy composites are resistant to solvents. Table 5 is a list of thermosets used for pump parts.

CANDIDATE FLUIDS FOR COMPOSITE PUMPS

This section discusses some of the more general liquids that are suitable for use in composite pumps.

Chlorine and Caustics Chlorine is used in the production of organic chemicals such as vinyl chloride, chlorinated solvents, pesticides, and fluorocarbons. Chlorine is also used in the pulp and paper industry, municipal water purification, sewage treatment plants, and in the electrolysis of sodium chloride to produce sodium hydroxide. Additional fluids in this category are as follows:

- Potassium hydroxide
- Sodium chloride solutions
- Seawater, brine

TABLE 2 Comparative advantages and disadvantages of the different styles of pumps

| Feature | Thermoset | Thermo-plastic | Flex-lined | Sprayed-lined | Rigid-lined |
|--|-----------|----------------|------------|---------------|-------------|
| Cut impellers available | Yes | Yes | Yes & No | Yes | Yes |
| Potential for damage to liner in operation or repair | Low | Low | High | High | Low |

FIGURE 3 Material selection for hydrochloric acid

- Sulfuric acid diluted up to 70%
- Hydrochloric acid
- Sodium hydrochloride
- Nitric acid up to 5%

Figure 3 shows that a composite pump can handle up to a 40% concentration of hydrochloric acid at 175°F (80°C).

Sulfuric Acid Figure 4 shows the operating range of a composite pump, pumping sulfuric acid.

Ferrous and Ferric Chloride Ferric chloride is used as an etching reagent in the production of printed circuit boards. It is also used as a coagulant in wastewater treatment. In metal pickling operations, ferric is produced when hydrochloric acid reacts with iron and steel. In all of these applications, composite pumps have replaced the more costly titanium pumps.

Ethylene and Propylene Candidate applications for composites of ethylene and propylene are

- Propylene glycol
- Ethylene glycol
- Diethylene glycol
- Propylene chlorhydrin

Dyes Acid, sulfur, and Diazo dyes can be used in composite pumps.

FIGURE 4 Material selection for sulfuric acid

Agriculture Chemicals Pesticides comprised of insecticides, herbicides, fungicides, and fertilizers can be severely corrosive to a composite pump. The chemical supplier should be contacted for their recommendations of materials suitable for use with their products.

Table 6 lists the maximum temperature and concentration of several liquids for various polymers.

INDUSTRIES USING COMPOSITE PUMPS

Pulp and Paper Composite pumps are used in bleaching and cooling of liquor preparation. The pumps can handle white, black, and green liquors. Other liquids suitable for composite pumps associated with this industry include

- Sulfuric acid
- Sodium chlorate
- Sodium hypochlorite
- Sulfur dioxide
- Chlorine
- Methanol
- Peroxide bleach
- Sodium chloride
- Chlorine dioxide

Metal Finishing Composite pumps are an excellent choice for use in this industry for two reasons:

- The chemicals used in electroplating, steel pickling, etching, anodizing, galvanizing, and plating do not chemically attack composites.
- Metal pumps can generate stray currents and could effect the plating process.

Composite pumps are natural electrical insulators, which makes them well suited for this industry.

Desalinization and Water Purification Composites can replace 316 stainless steel, duplex stainless steel and Alloy 20 on sea water distillation plants. On reverse osmosis equipment, composite pumps can be used for backwash, membrane blowdown, and intake screen wash.

Aqua Culture Composite pumps can be used for waste removal, seawater transfer, washdown, and filtering without adversely affecting sea life. This adverse reaction can occur with metal pumps. Metal pumps can have a chemical reaction with seawater and stray electrical currents generated by the pump can affect the pump's mechanical seal.

STANDARDS FOR COMPOSITE PUMPS

There are many composite pump designs for low-pressure and low-capacity use in the general-purpose market. For composite pumps in the "industrial chemical market," however, a separate standard ANSI/ASME B 73.5M has been written. This standard is similar to B73.1M for metal pumps in that it requires the same dimensional interchangeability, shaft deflection, and seal chamber requirements. The composite pump standard differs from the metallic pump standard in these areas:

- Basic working pressure is from 100 to 275 lb/in² (6.9 to 19 bar) depending on pump size.
- Nozzle flanges are Class 150 dimensions but not Class 150 rated.
- Hydrostatic pressure factor above working pressure will depend on size, rpm, and manufacturing process.
- Pressure-temperature limit will be based on a manufacturer-user agreement for the liquid and its concentration.
- The standard applies to both thermoplastic and thermoset composites.
- Casing, casing cover, and gland have a minimum corrosion allowance of two years.

Hydraulic Institute Material Selection Guide A material selection guide has been written with recommendations of what composite should be used with what type of liquid. This guide lists 150 liquids at various concentrations and temperatures and recommends suitable composites for applications. See References and Further Reading at the end of this section.

PUMP CONSTRUCTION

The pump section views in Figures 5 to 8 illustrate the construction of some composite pumps.

Components Figure 9 shows various pump components made from both thermoplastic and thermoset polymers. The enclosed impellers are made of thermoplastic resins

FIGURE 5 ANSI/ASME B73.5M pump (Flowserve Corporation)

because the front and back shroud can be ultrasonic- or vibration-welded together. Semi-open impellers can be made of either type of composite. On sizes greater than 6 in (152 mm) diameter, thermosets are usually used due to their superior strength over thermoplastics. When thermoplastics are used in larger impellers, a metal reinforcing skeleton is used for reinforcement. Casing and casing covers are made of either composite depending on the pump size and pressure rating.

The seal between the casing and cover is usually a shaped “O-ring” held by a groove running around the perimeter of the casing. The “O-ring” is compressed between the casing and cover with a ring of bolts around the casing’s perimeter.

Shafts are made of AISI 4140 or 316 stainless steel with a thermoplastic shaft sleeve for corrosion protection. Mechanical seals are of “outside” construction to prevent liquid from contacting the metal portion (springs) of the seal.

Bedplates Composite materials have several advantages over metals and other materials when used for bedplates. Composites do not rust, rot, or deteriorate in adverse environments. The composite bedplate maintains its shape over time. This assures that the pump shafts will stay in alignment, and the pump’s nozzle will not be stressed due to a sagging bedplate. The designed in features in a composite bedplate include an integral drip lip, slopping surface to collect drips, and ringed grout holes.

Disclaimer The data and notes included in this section are only for general guidance. No recommendations are intended as a guarantee by the author or other sources. Pump manufacturers and material suppliers can supply specific application information for their products when used with specific liquids in identified services and environments.

PUMP DRIVERS

SECTION 6.1

PRIME MOVERS

6.1.1

ELECTRIC MOTORS

AND MOTOR CONTROLS

A. A. DIVONA
A. J. DOLAN
J. R. HENDERSHOT

The two most common types of electric motors are *alternating current (ac) induction* and *direct current (dc) commutated shunt- or series-wound*. All electric motor configurations except one type (reluctance brushless) convert electrical energy to mechanical energy from the magnetic flux linkage of their two magnetic circuits. One of these circuits is in the stator and the other is in the bearing-mounted rotor. This flux linkage between the two magnetic circuits produces a moment of force at the rotor radius that results in a torque on the motor shaft causing shaft rotation. The speed of the rotation times the torque equals the output power at the motor shaft. This is, of course, the power used to drive a pump.

The basic difference between these two types of electric motors has to do with their electrical power source. The first type has been historically powered by 60 cycle (Hz) alternating voltages direct from the public utility power grid (50 Hz in most of Europe and some other parts of the world). For this type of motor, the speed is determined by the number of magnetic poles designed in the motor and the alternating sinusoidal frequency of the voltage from the power grid. Methods have been developed to alter the speed of an ac motor with a fixed number of poles and a fixed line frequency (it is also possible to wind such a motor with several poles for other speeds). However, the squirrel-cage induction motor remains without question the most common type of motor used to drive pumps. The reasons for this are worldwide availability, excellent reliability, excellent performance characteristics, and ease of replacement. As the pump industry continues to adopt variable speed motor/drives, the ac induction motor will likely continue to be by far the number one prime mover for most all types of pumps. This is also because of its adaptability to variable speed using ac inverters and vector drives.

The other motor type currently in use to drive pumps is the dc motor. Most of these applications are in the smaller sizes such as automotive and off road equipment. The overall use of dc motors for pump drives is predicted to decline.

The dc type of electrical machine also contains two magnet fields, one in each of the stator and rotor assemblies of the motor. Although the dc motor does not operate for its entire

useful life without maintenance on the mechanical brushes and commutator, it is still selected for some pump applications when only a dc voltage power source is available. It has been also selected in a limited number of instances where adjustable speed is required. The dc motor, powered by the voltage from storage batteries or from a dc generator, can be speed-adjusted by varying the voltage with a power supply. Its speed relationship to the voltage is linear and very useful for some pump applications such as constant displacement types, which require speed adjustment to set flow. [See Subsection 6.2.2.]

The more recent availability of permanent magnet brushless dc motors should offer a more reliable prime mover for these applications, with superior performance and long life benefits.

There are other types of electric motors considered for driving pumps. The reasons for this include the dramatic recent advances in power electronics and microprocessors, advances in motor materials such as permanent magnets, and advances in the pumps themselves. Besides the active interest in adjustable speed pumps, another reason for the interest in some newer motor types for pump applications is because of recent U.S. government regulations enacted to improve energy conservation by implementing motor efficiency mandates along with a time schedule. For example, the *U.S. Energy Policy and Conservation Act* of September 10, 1992 (EPACT) stipulates that all covered electric motor products must meet the efficiency levels per NEMA MG1 1993. The requirement covers all electric motors from 1–200 horsepower (1–150 kW) manufactured after October 24, 1997 that operate from 230/460 VAC power at 60 Hz line frequency. The U.S. Department of Energy approved test method to meet the new efficiency levels is per IEEE-112B. This regulation was originally intended for ac induction motors.

For those pump applications that require the motor torque to increase as the square of speed, these new, more efficient motors will run at higher speeds because their slip is less. This could cause an appreciable increase in overload within the motor. Overload could also result in other mechanical parts of the system. There are other ramifications resulting from these new requirements that must be carefully analyzed when selecting an electric motor, starter, or inverter. The resulting analysis might very well cause the selection to be some other electric motor type, such as a permanent magnet brushless dc, permanent magnet ac, synchronous (sine wave driven version of the brushless dc), or even a switched reluctance brushless dc motor. Each of these types must be powered with an inverter and a controller. However, the result can most likely offer adjustable speed with a very high efficiency over a wide speed range. This use of an inverter is required for each of those other types of motors mentioned. With the availability of the new vector controlled ac inverters (Section 6.2.2), the high-efficiency ac induction motor can also be applied for variable speed. This will eliminate the need for a soft starter frequently required with line fed motors. The elimination of the starter helps somewhat to offset the additional cost of the inverter.

TYPES OF MOTORS

Alternating-Current Motors

SQUIRREL-CAGE INDUCTION MOTOR By far the most common motor used to drive pumps is the squirrel-cage induction motor (Figure 1). This motor consists of a conventional stator wound with a specific number of poles and phases, and a rotor that has either cast bars or brazed bars imbedded in it.

The squirrel-cage induction motor operates at a speed below synchronous speed by a specific slip or revolutions per minute. The synchronous speed is defined as

$$N = \frac{f \times 60 \times 2}{p}$$

where N = speed, rpm

f = line-power frequency, Hz

p = number of poles

FIGURE 1 Exploded view of a typical squirrel-cage induction motor (Courtesy of Leeson Electric Corp.)

The percent slip is defined as

$$\% \text{ slip} = \frac{(N - s) \times 100}{N}$$

where s = slip, rpm

When the stator winding of a squirrel-cage induction motor is connected to a suitable source of power, a magnetic flux is generated in the air gap between the stator and rotor of the motor. This flux revolves around the perimeter of the air gap and induces a voltage in the rotor bars. Because the rotor bars are short-circuited to each other at their ends (end rings), a current circulates in the rotor bars. This current and the air-gap flux interact, causing the motor to produce a torque.

The squirrel-cage induction motor exhibits a characteristic speed-torque relationship that is determined by the resistance of the rotor bars. Thus, the desired speed-torque characteristics are obtained by selecting a metal of suitable resistance when designing the rotor bars. The slot shape and size for the bars in the rotor can be selected to achieve a certain rotor resistance.

Figure 2 suggests several typical speed-torque characteristics that have been standardized by NEMA (National Electrical Manufacturers Association), covering motor frames 143T through 449T. Motors larger than 449T may not have these same values, but generally have the same characteristic curves. Also, single-phase motors may not exhibit these characteristics and are defined specifically by NEMA with different values.

Most pumps are driven by NEMA B characteristic motors when operated from three-phase power sources.

WOUND ROTOR INDUCTION MOTOR The wound-rotor induction motor is in every respect similar to the squirrel-cage version except that the rotor is wound with insulated wire turns and this winding is terminated at a set of slip rings on the rotor shaft. Connections are made to the slip rings through brushes and in turn to an external resistor, which can be adjusted in ohmic value to cause the motor speed-torque characteristics to be changed. These types of motors have been used in some pump applications in the past, but due to

FIGURE 2 These curves are characteristic of NEMA frame size squirrel-cage induction motors through size 449T (typically through 300 hp–224 kW).

the availability of inverter-fed ac squirrel-cage induction motor drives, they are no longer very practical.

Figure 3 demonstrates the speed-torque characteristics of a wound-rotor induction motor for several resistor values. It will be noticed that increasing the external resistance of the control will cause the peak torque of the motor to be developed at lower speeds until the peak torque occurs at zero speed. Increasing the resistance beyond this value will cause the motor to have a limited torque as, for example, curves 4, 5, and 6. This motor can be used where torque control is required or where variable speed is necessary. In the variable-speed application, the rotor resistance is adjusted to produce a motor torque that matches the load torque at the specific speed desired. This system is not as useful and cost-effective as an inverter-fed ac induction motor due to the recent developments of power electronics and microprocessors.

SYNCHRONOUS MOTOR The synchronous motor is also similar to the squirrel-cage induction motor except that it operates at synchronous speed and its rotor is constructed with definite salient poles on which a field coil is wound and connected to a source of direct current for excitation. The most common synchronous motor is constructed with slip rings on the rotor shaft to connect the dc excitation to the field coils.

There are various means of providing the dc power to the slip rings:

FIGURE 3 Typical speed-torque characteristics of a wound-rotor induction motor (Westinghouse Electric)

FIGURE 4 Synchronous motor with direct-connected exciter (Electric Machinery Manufacturing)

1. **Static excitation** The power to be connected to the slip ring brushes on the motor shaft is obtained from a transformer and rectifier package external to the motor.
2. **Direct-connected exciter** This arrangement has a dc generator directly connected to the synchronous motor shaft (Figure 4). The dc power from this generator is connected to the brushes of the synchronous motor slip rings.
3. **Motor-generated exciter** The dc power for exciting the synchronous motor is generated by means of a remote motor-generator set operating from normal ac power, and the dc voltage from this motor-generator set is connected to the brushes of slip rings of the synchronous motor.

Another form of synchronous motor is known as the *brushless synchronous motor* (Figure 5). As the name implies, this motor has its rotating field excited without the use of slip rings for connecting the external direct current to the motor field. The construction of this

FIGURE 5 Brushless synchronous motor with ac generator mounted on the shaft with rectifier and control devices (Electric Machinery Manufacturing)

motor incorporates a shaft-connected ac generator. The field of the ac generator is physically stationary and connected to a source of dc voltage. The rotor of this ac generator is connected through a solid-state controlled rectifier mounted on the synchronous motor rotor and in turn connected to the synchronous motor field. This arrangement facilitates a connection between external excitation power and the rotating field of the synchronous motor through the air gap of the shaft-connected ac generator. The brushless synchronous motor has many advantages over the conventional slip-ring synchronous motor. Among these are the elimination of brushes and slip rings, which are high-maintenance items; the elimination of sparking devices, which are not permissible in certain atmospheres; and the use of static devices for field control, which are more reliable than conventional electromagnetic controls.

Synchronous motors are used for pump applications requiring larger horsepower ratings at lower speed conditions, as illustrated in Figure 6. Also, they are used on applications where a high power factor or a power-factor-correction capability is desired. Of less importance is the characteristic of the synchronous motor that it will always operate at synchronous speed (does not have a slip) regardless of load. Synchronous motors are started on their damper windings (the same as squirrel-cage induction motors), and when they have accelerated to within 5% of synchronous speed, the field is applied and the motor accelerates to synchronous speed (Figure 7). Typical characteristic curves are shown in Figure 8.

Direct-Current Motors Dc motors are only occasionally used to drive pumps. Most of the current applications for dc pump drives are in some form of automobile or off-the-road equipment due to the dc power from storage batteries. There are some other situations that might call for dc motor pump drives such as shipboard duty, railway applications, aircraft, mining installations, and some other emergency battery operations.

There are three types of dc motors available (Figure 9): shunt, series, and compound-connected.

Larger horsepower ratings of shunt-wound dc motors are frequently qualified as “stabilized shuntwound” motors and incorporate a series field similar to that of a compound wound motor. This is necessary to adjust the regulation of the shunt motor so as not to exhibit a rising speed-torque characteristic. It is important to be aware of the speed at which a dc motor will operate on pump applications because of pump performance guarantees.

The windings in the stators of the wound types are connected to the armature windings through brushes and a commutator three different ways to achieve different performance

FIGURE 6 Below 514 rpm, or powers greater than approximately 1 hp/rpm (0.746 kW/rpm), synchronous motors are a better selection than squirrel-cage induction motors because higher cost can generally be offset by higher power factor and efficiency (from *Power* special report, "Motors," June 1969).

FIGURE 7 Method of starting synchronous motor. (A) Typical field control (brush type) energizes the dc field to pull the rotor into synchronism as it comes up to speed. Field relay senses change in induced frequency as motor speeds up. (B) Damper winding is similar to a squirrel-cage rotor winding. It produces most of the starting torque, and the synchronous motor starts with essentially induction-motor characteristics (from *Power* special report, "Motors," June 1969).

characteristics (see Figure 3 for details). With the use of pulse width modulation (PWM) or silicon-controlled rectifiers (SCR), variable dc power supplies the armature voltage, which can be controlled along with a separate control for the field current (see Subsection 6.2.2). Using this control scheme, the dc motor can be used to control speed over a very wide range in a smooth manner. For example, constant voltage can be produced from zero rpm up to base design speed of the motor by armature control and constant power above base speed using flux weakening of the armature field. When operating from a constant voltage, dc motors are available to provide up to a 4 to 1 speed range with an adjustable dc field power supply. With this separate control scheme for both field and armature, a 100 to 1 speed range is easily achievable. Figure 9 summarizes the various field connection

FIGURE 8 Characteristics of synchronous motors depend on rotor design. Torque and current relations are influenced by synchronous speed. High-resistance cage produces high starting torque but low pull-in torque (from *Power* special report, "Motors," June 1969).

FIGURE 9A through C Types of dc motors. (A) Shunt motor has field winding of many turns of fine wire connected in parallel with the armature circuit. The interpole winding aids commutation. (B) Series motor has field in series with the armature. Field has a few turns of heavy wire carrying full-motor current flowing in the armature. (C) Compound motor has both a shunt and a series field to combine characteristics of both shunt- and series-type motors in the same machine (from *Power* special report, "Motors," June 1969).

schemes for dual wound dc machines with mechanical commutation systems. Figure 10 illustrates typical characteristics of the dc motors discussed. Figure 11 shows the equivalent circuit of a permanent magnet type dc motor.

Permanent Magnet (PM) Brushless Motors The permanent magnet brushless dc motor has been in existence for about three decades and is finally being widely used for many applications. Its being brushless has frequently been mentioned as justification for its cost, higher than most other motor types. However, the PM brushless motor has two other features that are arguably more important than the fact that it contains no mechanical brushes and commutator for commutation of the phase windings to the power source. First, it produces the highest continuous output power per unit volume of any motor yet invented. The other important virtue of a PM brushless motor is that it produces its output power with the least input power. For a given size and output performance envelope, it has the most efficient motor of any electric motor yet invented. With the emphasis on reducing power consumption, this type of motor will be used in many pump applications. In addition, and perhaps most importantly for the application of pumps, the PM brushless motor possesses one other very important feature or use of the permanent magnets contained within the rotor assembly. Although the magnets are there to supply a magnetic field from the rotor to pass through the air gap of the motor into the stator, these same magnets can serve as a magnetic coupling. If a sleeve-shaped liquid barrier made of a suitable material to be impervious to the liquid is fitted between the rotor and stator, the PM brushless can be used as the best hermetically sealed wet motor known. There are, of course, many possible configurations of this PM brushless hermetic motor concept. These PM brushless hermetic motors can be configured as axial gap, radial gap inside

FIGURE 10 Speed, torque, and power characteristics of dc motors (from *Power* special report, "Motors," June 1969)

V = Terminal voltage, volts
 R_a = Armature resistance, ohms

 E_g = Back-EMF, volts

FIGURE 11 The equivalent circuit of a dc motor with a permanent magnet stator

rotor, or radial gap outside rotor motors (Figure 12). The choice depends upon the best way to design the pump integration.

All PM brushless motors must be powered with an electronic inverter and controller, which can be used for controlling pump performance in controlled loop systems of all types. The electronic drive can be a simple square wave, a six-step trapezoid type, or a sinusoidal drive. Also, some sort of electronic remote or motor mounted shaft position system that is no different than that used for an ac induction vector drive is required.

Three permanent magnet choices can be used for these motors. The lowest priced magnet material is known as ferrite or ceramic with a magnetic flux output of about one-third

FIGURE 12 Inner, outer, and axial rotor PM brushless motor choices for pump drives

to one-half of the other two magnet choices. By careful design, this magnet material can be used for 50 hp (37 kW) and up in PM brushless machines to keep costs competitive with other machine types. For brushless motors less than 50 hp (37 kW), the two high energy or rare earth magnet grades are frequently useful. The more expensive of the two, Samarium Cobalt, is used for high temperature and other hostile environment pump motor applications. The newer rare earth magnets, known as Neodymium Iron Boron, are much lower in cost, with the highest useful magnetic flux at moderate operating temperatures. Either the magnets can be assembled onto the surface of the rotor or they can be imbedded within the laminated rotor structure. In either design, the rotor can be made to be quite robust and yield a very long useful operating life. In fact, the only failure modes for PM brushless motors have to do with bearings or winding insulation. Figure 13 shows examples of large PM brushless motors.

The speed can be controlled to greater than 100 to 1 if required with constant power over the highest speed range of any other motor type. The efficiency remains very high over the entire speed range. There are many design possibilities including axial gap and outside rotor configurations. For example, because of the high magnetic strength of the permanent magnets, the rotor of a PM brushless motor can also serve as the impeller of a pump that is integrated with the motor in a hermetically sealed package with no shaft seals. Utilizing the axial-gap rotor configuration of Figure 12, the concept is illustrated in Figure 14. Commercially significant impeller torque levels can be generated by the PM brushless motor in this configuration¹. This eliminates the need for a separate magnetic coupling or larger-size canned induction motor (see the discussion at the end of this section and in Section 2.2.7).

The PM brushless motor can be driven with either square wave currents over a 120 degrees electrical commutation angle or with sinusoidal currents over 180 degrees electrical commutation angle. The latter scheme generally yields lower torque fluctuations, which is sometimes important for pump applications. Either drive requires shaft angle feedback data to tell the phases when to be powered. This feedback data is also a requirement for vector driven ac induction motors. The sensor used for this feedback can be as simple as *Hall* switches mounted in the motor that send out a pulse to the controller each time a rotor magnetic pole changes polarity as the motor rotates. An optical encoder or a *resolver* can also be used for this purpose. Several sensorless or remote sensors have been developed that capture the rotor angle location from the stator phase windings so a shaft-mounted sensor is not required.

FIGURE 13 Large horsepower (kW) high-performance permanent magnet inside rotor brushless motors (courtesy of Pacific Scientific)

FIGURE 14 Permanent magnet brushless motor integrated into a seamless pump. Permanent magnets are mounted on the impeller, which serves as the rotor of the motor. (Courtesy of Flowserve Corporation)¹

Switched Reluctance Brushless Motor The SR brushless dc motor is one of the oldest motors known, but it has not been used much until recently. Its main feature is that it is a true brushless motor with most of the virtues of its PM cousin, but it does not require permanent magnets. This feature is a great benefit for the PM brushless motor when it is used in a hermetic pump application. However, the PM brushless motor is limited in the availability of practical sizes because of the cost of permanent magnets. As the

FIGURE 15 Switched reluctance brushless dc motor, (6) rotor poles, (2) stator poles per phase

PM motor gets larger in power and frame size, the cost of the magnets becomes prohibitive. The ac induction motor is still a very good choice for most high-power applications, even when adjustable speed is needed. However, as centrifugal high-speed pumps gain popularity, the ac induction motor has difficulty surviving the forces on the rotor. Proponents of switched reluctance motors point out its inherent robustness. The rotor of the SR motor is so simple and rugged it can survive very at high speeds as well as in a variety of other unusual environmental conditions. Figure 15 shows the typical cross section of a switched reluctance motor, illustrating how simple this motor is with phase coils placed around the stator poles. The rotor consists of a set of magnetic steel gear-shaped laminations taken from the bore of the stator laminations. They are stacked and retained on the motor shaft. No magnets or windings of any kind are required to produce torque. The SR motor is said to be a doubly salient pole machine. The torque is produced by the magnetic attraction of the closest rotor poles to those stator poles which are magnetized by the phase coils. There is an abundance of technical information regarding the performance details of this technology. The important point is that the SR motor is an excellent choice for high-speed high-powered centrifugal pumps.

There is a considerable difference in the inverter topology for the SR motor as compared to either the PM brushless or the ac induction motor. The SR machine must be driven as a unipolar machine rather than a bipolar motor like the other two. This means the standard ac inverter cannot be used for the SR motor. The phases are each connected to the dc power in parallel rather in the standard bridge fashion with all of the phases connected together at a center tap. Figure 16 shows the normal power circuit for the (4) phase SR motor shown in Figure 15. The same circuit is applicable for both two phase or three phase. It is essentially an independent half bridge circuit for each phase. Certain two phase designs are very cost effective for high speed pump drives that are required to rotate in only one direction without the need for reversing.

MOTOR ENCLOSURES

Electric motors are manufactured with a variety of mechanical enclosure features to provide protection to the working parts for specific environmental conditions. Although these

FIGURE 16 Power control circuit for (4) phase SR motor, (6) transistors, (6) diodes, (3) current sensors, (1) capacitor, and (6) motor lead connections

special enclosures are classified, they are not, for reasons of economy, available for all size motors. The electric motor industry has incorporated a number of specific enclosure classifications on standard designs of small- and medium-size motors.

The following list describes the motor enclosure specifications available for polyphase ac induction motors used with pumps. This availability depends on demand. Furthermore, the PM brushless and SR brushless motors might not be available in some of the enclosures listed. In general, totally enclosed motors are required for most integral horsepower (kilowatt) pump applications regardless of the motor type. In some instances, such as high-speed centrifugal pumps with integral motors, the motor is furnished to the pump manufacturer as a rotor and stator parts kit. The motor is then included in the pump enclosure.

OPEN This enclosure permits passage of external cooling air over and around the windings and rotor of a motor and normally includes no special restrictions to ventilation other than those that are inherent in the mechanical parts of the motor. Most designs include openings at each end of the motor frame either in the bearing end frame or openings around each end of the frame.

OPEN DRIPPROOF This is an open machine with ventilating openings designed to permit satisfactory operation when liquids or solids fall on the machine at any angle up to 15° from the vertical. Openings are normally in the bottom portions of the frame assembly. This construction includes mechanical baffling to prevent materials from entering the machine within these limits.

SPLASHPROOF This is an open machine with ventilating openings designed to permit satisfactory operation when liquids or solids fall *directly* on the machine or come toward the machine in a straight line at any angle up to 100° from the vertical.

GUARDED ENCLOSURE This provision limits the size of the ventilating opening to prevent accidental contact with the operating parts of the motor other than the shaft.

SEMI-GUARDED This is an open construction where some of the ventilating openings are guarded and the remaining openings are left open.

OPEN, EXTERNALLY VENTILATED This motor is ventilated by a separate motor-driven blower mounted on the motor enclosure (piggyback construction).

OPEN, PIPE-VENTILATED This motor is equipped to accommodate an air-inlet duct or pipe for accepting cooling air from a location remote from the motor. Air is circulated in the motor either by its own internal blower parts or by an external blower, in which case the motor is said to be *forced-ventilated*.

WEATHER-PROTECTED TYPE I This is an open-construction motor with ventilating openings to minimize the entrance of rain, snow, and airborne particles to the motor's electrical parts, and with the openings arranged to prevent the passage of a $\frac{3}{4}$ -in (19-mm) round rod.

WEATHER-PROTECTED TYPE II This construction has the same features as the type I machine, but in addition the intake and discharge ventilating passages are designed so high-velocity air and airborne particles blown into the machine by storms can be discharged without entering the internal ventilating passages of the motor leading to the electrical parts. The ventilating passages leading to the electrical parts of the motor are provided with baffles or other features to allow at least three abrupt changes of at least 90° for the ventilating air. The intake air path and openings are proportioned to maintain a maximum of 600 ft/min (3 m/s) velocity of the entering air.

TOTALLY ENCLOSED This motor is designed without air openings, so there is no free exchange of air between the inside and outside of the motor frame; the construction is not liquid- or airtight. Normally the rotor has die-cast air circulating fins at each end to circulate the trapped inside air and improve convection cooling to the frame.

TOTALLY ENCLOSED, FAN-COOLED This totally enclosed motor is equipped with an external fan operating on the motor shaft to circulate external air over the outside of the motor. Most motors have cast fins the length of the frame to increase surface area and take advantage of the fan cooling.

EXPLOSIONPROOF This totally enclosed motor is designed to withstand an internal explosion of gas or vapor and constructed to prevent ignition by the internal explosion of gases or vapors outside the motor.

TOTALLY ENCLOSED, PIPE-VENTILATED This motor enclosure is similar to the open, pipe-ventilated motor except that it is equipped to accept outlet ducts or pipes in addition to inlet ducts or pipes.

TOTALLY ENCLOSED, WATER-COOLED This is a totally enclosed motor cooled by water passages or conductors internal to the motor frame.

TOTALLY ENCLOSED, WATER-TO-AIR HEAT EXCHANGE This is a totally enclosed motor equipped with a water-to-air heat exchanger in a closed, recirculating air loop through the motor. Air is circulated through the heat exchanger and motor by integral fans or fans separate from the rotor shaft and powered by a separate motor.

TOTALLY ENCLOSED, AIR-TO-AIR HEAT EXCHANGE This motor is similar to the water-to-air heat exchanger motor, except external air is used to remove the heat from the heat exchanger instead of water.

SUBMERSIBLE This totally enclosed motor is equipped with sealing features to permit operation while submerged in a specified medium at a specified depth.

Environmental Factors The environmental conditions of the pump application dictate the type of motor enclosures to be used. A brief set of rules for selecting motor enclosures follows.

DRIPPROOF For installation in nonhazardous, reasonably clean surroundings free of any abrasive or conducting dust and chemical fumes. Moderate amounts of moisture or dust and falling particles or liquids can be tolerated.

MILL AND CHEMICAL MOTOR (TO NEMA FRAME 449T) For installation in nonhazardous, high-humidity, or chemical applications free of clogging materials, metal dust, or chips, or where hosing down or severe splashing is encountered.

TOTALLY ENCLOSED, NONVENTILATED OR FAN-COOLED For installation in nonhazardous atmospheres containing abrasive or conducting dusts, high concentrations of chemical or oil vapors, where hosing down or severe splashing is encountered.

TOTALLY ENCLOSED, EXPLOSIONPROOF For installation in hazardous atmospheres containing:

- Class I, Group D* Acetone, acrylonitrile, alcohol, ammonia, benzene, benzol, butane, dichloride, ethylene, gasoline, hexane, lacquer-solvent vapors, naphtha, natural gas, propane, propylene, styrene, vinyl acetate, vinyl chloride, or xylenes
- Class II Group G* Flour, starch, or grain dust
- Class II, Group E* Metal dust including magnesium and aluminum or their commercial alloys.
- Class II, Group F* Carbon black, coal, or coke dust

NOTE: Under Class 1 only, there are two divisions that allow some latitude on motor selection. Generally, Class 1, Division 1 locations are those in which the atmosphere is or may be hazardous under normal operating conditions, including locations which can become hazardous during normal maintenance. An explosionproof motor is mandatory for Division 1 locations. Class 1, Division 2 refers to locations where the atmosphere may become hazardous only under abnormal or unusual conditions (breaking of a pipe, for example). In general, a motor in a standard enclosure can be installed in Division 2 locations if the motor has no normally sparking parts. Thus, open or standard totally enclosed squirrel-cage motors are acceptable, but motors with open slip rings or commutators (wound rotor, synchronous or dc) are not allowed unless the commutators or slip rings are in an explosionproof enclosure.

BEARINGS AND LUBRICATION

Very large horsepower (kilowatt) motors are generally supplied with oil-lubricated sleeve bearings with oil supplied from a reservoir. In some cases, pressurized oil lubrication systems are installed by the pump manufacturer along with hydrodynamic thrust bearings. All NEMA frame induction motors are available with ball bearings. These standard ball bearings are normally permanently grease lubricated. The bearings used in a motor must be sealed to keep the lubricant inside the bearings and keep contaminants from getting into the bearings. Double-sealed bearings are common for many pump applications.

Ball bearings are subject to early failure when used in electric motors driven by PWM inverters. This very common problem must be addressed. It is caused by the high carrier frequency used in the inverter to generate the sinusoidal currents for each phase. This results in generation of high common-mode voltages inside the phase windings of the stator. Because there is an excellent electrostatic coupling between the stator/frame and the rotor from the windings, a voltage is induced in the shaft. The ball bearings represent the least-resistant path for a short circuit to the stator. However, the balls seldom actually contact the races because of the film of grease or oil in between. When the voltage builds up in the shaft until it is greater than the insulating capability of the film of lubricant, the voltages arc across the lubrication gap and a flashover current goes through the bearing. In a relatively short amount of time, the bearing races will become grooved, causing the bearings to become noisy. Metal particulate will then egress from the bearing surfaces as the process continues, causing catastrophic bearing failures after a few months.

Therefore, all electric motors that are driven by PWM drives must have a shaft grounding system to provide a low resistance path between the shaft and the motor

frame. There are other solutions to this potential problem, which can be discussed with the motor supplier.

Sleeve Bearings Motors that use oil-impregnated porous sleeve bearings are lubricated with an oil-soaked wick. These bearings are available in motors up to approximately 1 hp (0.75 kW). Sleeve-bearing motors larger than 1 hp (0.75 kW) are ring-lubricated. Lubricating oil is drawn up from the bearing sump to the bearing by a ring that rolls over the top of the motor shaft as the shaft rotates. Larger motors, having bearing heat losses that cannot be dissipated directly, may require the use of a pressurized lubrication system wherein oil is pumped into the bearings and allowed to recirculate through a heat exchanger. The oil delivered to each bearing is metered to provide only the required amount. A lubrication system composed of heat exchanger, sump, and pump is normally common to a number of bearings, rather than having a single lubricating pump for each bearing. Other types of bearings must be used in place of, or in addition to, sleeve bearings when thrust loads are present. Smaller sleeve bearings are in the form of a cylindrical shell and are usually made of bronze or steel-backed babbitt metal. Larger sleeve bearings are usually split on a horizontal centerline, allowing easy assembly and disassembly for inspection and replacement. The bearing housing is also split on the horizontal centerline and held together with bolts between the top and bottom halves.

Rolling Element Bearings All new electric motors manufactured to NEMA standards use grease-lubricated ball bearings with high radial and thrust load capacities. They are axially pre-loaded to eliminate any radial or axial play for quiet operation and long life. Most motor end frames include an outer race locking plate on the shaft end bearing to prevent race rotation due to output shaft loads. These bearing mounting features are required for high performance, long life, and high efficiency operation. Most motor manufacturers provide their larger frame sizes with grease fittings for relubrication during the lifetime of the motor. The smaller frames use bearings that are grease-packed and sealed for life at the factory and cannot be relubricated.

NEMA motors subject to very high loads and operating temperature in the larger frames may require oil lubrication to the rolling element bearings. This can be by either oil circulation within the bearing frame or from a pressurized lubrication system similar to that used with sleeve bearings. In addition, for motors required to carry very high thrust loads, quite often in only one direction, taper or spherical roller thrust bearings may be used.

Hydrodynamic Thrust Bearings Certain types of pump applications, such as very large vertical pumps, exhibit very high thrust loads that cannot be accommodated by rolling element bearings. Hydrodynamic bearings, usually with tilting, self-leveling thrust pads, are used for very high thrust loads. These bearings are sometimes referred to as "Kingsbury-type" in recognition of the original manufacturer of this bearing type. This type of bearing is oil-lubricated from a self-contained oil sump or an external pressurized pumping system, depending on size and rating.

MOTOR INSULATION

Insulation systems must be used in a motor to electrically insulate the windings from the mechanical parts of the motor as well as to insulate the phase winding conductors from one another. Extra insulation is also required between any adjacent phase windings for 230 or higher voltage motors. In general, the higher the operating voltage, the better the insulation system must be.

All NEMA-designed electric motors are manufactured with cord laced end turns to assure that they are positioned so they cannot touch any mechanical parts. In addition, the phase windings are nearly always impregnated with a varnish by either dipping or trickling into the heated end turns. The purpose of this is to secure the conductors to prevent them from vibrating between one another, which would wear through the wire insulation

and cause turn-to-turn shorts. This stator varnish also provides some additional insulation protection to the system. For example, this coating makes the windings resistant to ambient conditions such as moisture. Consequently, a motor insulation system is very complex, utilizing several different materials, parts, and processes to effectively insulate the windings. The parts considered in an insulation system include slot cells, phase barriers, conductor insulation, slot wedges, end turn supports, tie material, and winding impregnation material.

Since the introduction of PWM inverters for use with all types of variable speed drives, such as ac induction, PM brushless and switched reluctance brushless, a new insulation system failure mode has emerged. This is a most significant problem in installations where the inverter is located 50 ft (15 m) or more away from the motor. The long motor lead cables used in these applications cause very high voltage spikes not present at the inverter end of the lead cables. These voltage spikes across the first turns of each phase winding result in the degradation of the wire insulation due to the corona insulation failure. Special magnet wire insulation and motor manufacturing methods are available to overcome this problem. Therefore, if an inverter is to be used to drive a pump motor with long connection cables, an “inverter duty” motor should be specified.

There are four basic classes of insulating materials currently recognized by the motor industry. Each differs according to its physical properties and can withstand a certain maximum operating temperature (frequently termed total *temperature* or *hot-spot temperature*) and provide a practical and useful insulation life. The insulation classes and their maximum operating temperatures are

| | |
|---------|-------|
| Class A | 90°C |
| Class B | 130°C |
| Class F | 155°C |
| Class H | 180°C |

Those factors that contribute to the maximum operating temperature of a motor insulation system are the ambient temperature, the temperature rise in the motor winding caused by motor losses, and any overload allowance designed into the motor (service factor).

The current standard for motors within the range of NEMA ratings (frames 140T to 449T) requires nameplate marking for the maximum allowance ambient temperature, the power rating, the associated line current needed to develop this power, the class of insulation used, and the service factor provided. Motors larger and smaller than NEMA frame sizes have nameplate marking for maximum allowable ambient temperature, temperature rise in degrees Celsius either by thermometer or resistance measurement, power rating, line current needed to develop this rating, and any service factor provided.

In addition to ambient temperature, there are several additional environmental conditions that must be considered when applying an electric motor. In applications where chemical fume or moisture levels are abnormal and can cause decomposition of an insulation system, standard insulation will be inadequate. These applications require a motor with a premium insulation system that will incorporate highly resistant components and may include special impregnation techniques. Chemical fumes and moisture can also be destructive to the mechanical parts of a motor, and special protective treatment should be provided to these parts. NEMA frame-size motors have a special motor for chemical industry applications that has standard features to resist these environmental factors. For example, these motors usually contain shafts made from stainless steel.

Applications with excessive vibration can destroy a winding and damage the mechanical parts of a motor. In such cases, it is advisable to provide (1) extra treatment for the winding to ensure that it is rigid and will not vibrate and chafe the insulating materials and (2) a mechanical construction that will have the strength to withstand the above.

If abrasive dust is present, the motor insulation should be protected with a resilient surface coating to withstand the impact of the abrasive particles.

Because all insulation systems employ components that can in some degree support fungus growth in tropical locations, motors applied in such areas should incorporate fungus-proofing treatment on the insulation.

Obviously, applications exhibiting a combination of any or all of the environmental conditions discussed should have special protection for each condition. Applications in unusual environmental conditions may require special protection and should be discussed with the motor manufacturer or distributor.

COUPLING METHODS FOR PUMP APPLICATIONS

Direct Coupling Pumps are frequently directly coupled to motors, and where the pump is not close-coupled, it is usually coupled by means of a flexible coupling. The use of a flexible coupling permits minor misalignment (angular and parallel) between motor and pump shafts. The use of some older style flexible or solid couplings could cause severe radial and axial loads on the motor bearings. Since the development of the flexible disk couplings, the earlier coupling designs have largely disappeared, as have the severe loads resulting from misalignment. The flexible disk coupling is capable of transmitting very high torque for its size, with minimum radial and axial forces on the shafts resulting from misalignment. [See Subsection 6.3.1.]

Close-Coupling Close-coupled pumps have become very popular for certain applications. In this arrangement, no coupling is provided between the pump and motor shafts and the pump housing is flange-mounted between close-tolerance fits on both the motor and the pump flanges. The pump impeller is mounted directly on the motor shaft. Care must be taken in this arrangement to ensure that the motor shaft runout or axial movement plus machine tolerances do not cause interference between the pump housing and its rotor. This is usually not a problem if properly fitted ball bearings are used in the motor. The motor shaft material must be compatible with the fluid being pumped, and if the pump impeller is held in place by a nut, the threat must respect the rotation of the motor. High-pressure close-coupled pumps of a nonbalanced design can cause excessive shaft thrust, which may be incorporated in the motor bearing capacity. It is always good practice with close-coupled pumps to provide some form of flinger on the motor shaft to prevent liquids that leak past the pump seal from entering the motor bearing.

Flanged Motors Flanged motors allow an easy means of aligning pump housings with motors. This construction is usually in the form of a vertical mounting in which the motor is set on top of the pump and the pump supports the motor weight. The pump and motor shafts are normally coupled, and those comments made under the subject of direct-coupling methods are applicable. Also, as in the case of coupled pumps, this construction permits thrust forces that must be considered when selecting a motor if the pump does not have a thrust bearing.

A further extension of flange motors includes the vertical hollow-shaft motor. With this design, a variable length of shafting connects the pump and motor. The pump shaft passes through the center of the motor bore, and the motor torque is imparted to the pump shaft by a suitable coupling at the top of the motor. The weight of the shaft and the pump impeller and the force of the hydraulic thrust are assumed by the motor bearings.

The coupling on the motor can be made a *self-release coupling* (Figure 17) to prevent the motor from delivering torque to the shaft in the event the motor is started in the wrong direction and to prevent reversed motor rotation from unscrewing the threaded joints between lengths of pump shafting.

Another modification to a coupling is a nonreverse *ratchet* (Figure 18), which prevents the remaining head of liquid in a pump from rotating the pump in the reverse direction when the pump is stopped. This prevents possible overspeeding of the pump and motor when the pump is connected to a large reservoir and most of the total pump head is static. This also prevents a pump with a long discharge column pipe from running in reverse with no liquid in the upper portion of the pipe to lubricate the line shaft bearings. Starting a pump capable of back spinning is also prevented.

FIGURE 17 Self-release coupling connecting pump head shaft to hollow shaft of vertical motor disengages as a result of pump shaft couplings unscrewing (U.S. Electrical Motors).

FIGURE 18 Section of vertical hollow shaft motor showing nonreverse ratchet. Spring-loaded pins ride on ratchet plate in one direction only (General Electric).

PERFORMANCE

Ac induction motors are designed to produce their rated power at a certain speed at a specific line voltage, line frequency, and ambient temperature. These motors will also operate at a specific efficiency and power factor when all of these conditions are met. The normal operating conditions of a motor are stipulated on its nameplate with values for power,

speed, ambient temperature, and frequency. If the operating conditions are different from the nameplate ratings, the motor performance will be altered. Many of the newer PM and SR brushless motors are designed to produce their rated output power over a wide speed range. A high efficiency ac induction motor can also perform similarly if a Flux Vector Inverter is used for control.

Voltage Ac motors are designed to operate satisfactorily at their nameplate voltage rating with a $\pm 10\%$ variation from nameplate voltage when operating at rated nameplate frequency. This dictates that the motor will develop rated power and speed to a pump and will operate at a safe insulation temperature over the range of voltage. The motor torque will vary directly with the square of the applied voltage divided by the nameplate voltage. This affects the peak torque of the motor and will cause the motor speed-torque curve as shown in Figure 2 to be altered. Within the $\pm 10\%$ voltage band, a motor can be expected to accelerate and operate a pump safely and continuously. A motor should never be expected to operate continuously beyond the $\pm 10\%$ band. If the voltage varies more than $\pm 10\%$, the pump and motor may not operate satisfactorily.

For example, assume a pump is operated by a NEMA design B motor (refer to Figure 2) that will produce 200% pull-out torque at rated voltage. If the line voltage were to fall to 70% of the rated name-plate voltage, the motor would produce only 49% of its peak torque value. The pull-out torque of the motor would then become $0.49 \times 200 = 98\%$ of rated torque. It then becomes very doubtful whether the motor will be able to sustain the pump load, and the motor can be expected to lose speed, stall, or become overloaded. Certainly, it will also heat up, which will shorten the expected life of the bearing lubrication and winding insulation system.

In a similar sense, a motor may be unable to accelerate a pump if low line voltage exists. In the example previously discussed, this same motor develops 150% of rated torque when started at zero speed and rated voltage. If the line voltage is again 70% of nameplate voltage, the motor will develop $0.49 \times 150 = 73\%$ of rated torque. This may be a problem with certain types of pumps, such as a constant displacement pump. It is conceivable that this would not be a problem in starting a centrifugal pump because of its square-law speed-torque characteristics. If the motor voltage never increased beyond 70%, the centrifugal pump would not reach normal operating speed. An exception to this rule is the commutating ac motor, for which a $\pm 6\%$ voltage variation is allowable.

Varying motor voltage from nameplate rated voltage will also affect the motor operating speed, power factor, and efficiency established for rated voltage and load. Most polyphase ac induction motors will operate at several rpm faster than nameplate speed at 10% over voltage and several rpm below nameplate speed at 10% under voltage. The speed of a synchronous motor is determined by the line frequency of the alternating voltage not the voltage level. Therefore, voltage variation has no effect on the speed of a synchronous motor. However, voltage variation does effect maximum torque output of a synchronous motor.

Dc motors can also be operated over a $\pm 10\%$ voltage range from nameplate rated voltage. However, it should be recognized that different types of dc motors will have different speed and torque characteristics over the voltage range. This should be taken into account when meeting pump performance requirements.

One of the most common applications for dc motors has been for metering pumps because of their ease of setting the speed to precisely meter the fluid being pumped. Although a voltage variation would change the pump speed, it is customary to include a speed control loop with the dc supply to maintain constant speed in spite of line voltage variations.

Frequency Ac induction motors will operate satisfactorily at rated load and voltage with a frequency variation up to $\pm 5\%$ from rated nameplate frequency. However, the speed of the motor will vary almost directly with the line frequency. The speed of a synchronous motor will vary directly with applied frequency. The combined variation of voltage and frequency must not be more than $\pm 10\%$ from rated nameplate voltage and frequency, provided the frequency variation does not exceed $\pm 5\%$ from rated nameplate frequency. The reason is that frequency variation from the nameplate frequency will cause motors to

operate at a power factor and efficiency other than those established for rated frequency. Any electric motor such as PM or SR brushless and even ac induction, which is powered from an inverter, is unaffected by frequency variations.

Speed and Speed Range Synchronous and induction motors were originally expected to be operated at one specific speed when powered from line voltage and frequency. However, with the availability of inverters, this is no longer the case. In fact, the use of inverters for driving induction motors is expanding at a fast pace as the merits and benefits of adjustable speed are being realized. The use of speed controlled PM and SR brushless motors along with their inverters and controllers allow the pump application to take advantage of the usefulness of adjustable speed. Using the inverter with any of these types of motors eliminates any difficulties from speed variations from the past. This is because most inverters have a speed control loop that will automatically maintain the set speed.

Acceleration A motor must be capable of accelerating as well as driving a pump at rated speed and power. The acceleration can be analyzed by examining a typical pump-motor combination involving a centrifugal pump driven by a six-pole squirrel-cage induction motor rated 10 hp (7.46 kW) with NEMA design B torque characteristics. The curve in Figure 19 demonstrates this combination when the pump is loaded and the motor is operating at nameplate frequency and voltage. It will be noted that the torque produced by the motor at any speed must be greater than the torque required by the pump when up to speed. The excess torque at any speed is available to accelerate the motor, coupling, and pump rotating parts.

NEMA has provided a handbook for motion control that outlines the fundamental equations for the required torque calculations to accelerate any inertial loads to a predetermined speed. For the use of ac induction motors that are line-fed with constant voltage and frequency, the formulas are used to calculate the time to the motor slip from synchronous speed for a given total rotating inertia. For the use of inverter-fed ac induction, PM or SR brushless motors, the formulas are used to determine the torque required to accelerate the total rotating inertial load to the desired speed in the desired time.

The fundamental equations for motion, which include torque, inertia, time and acceleration relationships, are given below. They can be used for motor selection analysis for pumps. For example, if the torque available from an induction motor is known, the equation can be solved for the acceleration time of the system inertia (from NEMA "Programmable Motion Control Handbook").

FIGURE 19 Typical speed-torque characteristic curves for a centrifugal pump and a squirrel-cage induction, NEMA design B motor. Excess torque accelerates pump.

$T_{TOTAL} = T_A + T_C$: Total torque = Acceleration torque + constant torque

$T_A = J_{TOTAL} \times \alpha$: Acceleration torque = Inertia \times Angular acceleration

$\alpha = \frac{\omega_{max}}{t_a} \times 2\pi$: Angular acceleration = Max RPM/acceleration time

T_C = Torque from all other constant forces, friction, windage, preload, and so on.

NOTE: Use consistent units depending on whether U.S. Customary or SI.
The time to accelerate the pump is equal to

$$\text{in USCS units} \quad t = \frac{WK^2 \times \Delta \text{rpm}}{308T}$$

$$\text{in SI units} \quad t = \frac{MK^2 \times \Delta \text{rpm}}{9.55T}$$

where t = time, s

WK^2 = total weight (force) moment of inertia, lb \cdot ft²

Δrpm = change in speed

T = torque, lb \cdot ft ($N \cdot m$)

MK^2 = total mass moment of inertia, kg \cdot m

Because the difference in torque is not uniform over the speed range, the curve (Figure 19) can be analyzed by assuming discrete changes in speed and an average torque over this change in speed. A time period can be calculated for each discrete speed change, and all time values can be totaled to obtain the complete acceleration time.

Increasing the inertia of the pump, the operating speed of the pump and motor, or the torque required by the pump at any speed will result in a longer acceleration time, which may not be possible for the motor. Each motor can operate at a reduced speed and at a torque in excess of rated torque for a given time. Beyond this time, the windings and/or rotor can be damaged. The use of an inverter-driven ac induction SR or PM brushless motor eliminates all of these problems associated with the use of line-fed ac induction motors. This is due to the torque control capability of the inverter/motor drive system using current control. The limit on the ability of the adjustable speed drive to control acceleration is a function of the current capability of the inverter (as long as the thermal limit of the motor has not been exceeded).

When an application is analyzed and found to present an acceleration-time problem, consideration should be given to

1. Unloading the pump during acceleration
2. Reducing the inertia of the rotating parts
3. Selecting a larger motor
4. Considering an adjustable speed motor and drive

When very large pumps are started, the line voltage will sometimes drop because of the high starting current, which causes the motor torque to be reduced by the square of the voltage ratio. Naturally, the acceleration time is greater because of the reduced torque produced by the motor. This will not hamper the ability of the motor to accelerate the pump as long as the motor develops more torque than is required to drive the pump at any speed over the accelerating range. The use of SR or PM brushless induction motors eliminates this problem because these motors do not draw high inrush currents. In fact, the starting current is controlled very precisely.

A similar analysis can be made for synchronous motors after the accelerating speed-torque curve for the motor is known. It should be recognized that a synchronous motor operates as a squirrel-cage induction motor up to the moment of synchronization. At that time, the synchronous motor must have an additional capability of synchronizing torque,

frequently called *pull-in torque*, to accelerate the motor from subsynchronous to synchronous speed. If the motor cannot develop enough torque at its synchronous speed, it will pull out or stall. When this type of motor is used for a pump, it is advisable to unload the pump during acceleration operation to reduce the torque required from the motor for acceleration.

When using a synchronous motor, attention should always be given to the breakaway torque that is required to start the pump from zero speed. This is particularly important with constant displacement pumps, where the pump will operate at a constant torque over the entire accelerating speed range. Again, a better selection might be an inverter-driven ac induction motor, SR or a PM brushless motor.

Service Factor Motors are available with service factor ratings that range from 1.0 to as high as 1.5. A service factor implies that a motor has a built-in thermal capacity to operate at the nameplate power times the service factor stamped on the nameplate. It should be noted, however, that when the motor is operated at the service factor power, the motor will operate at what is termed a *safe temperature*. This means that the motor will operate at a total temperature that is greater than the temperature for a motor designed for the same power with a 1.0 service factor. Consequently, it is not advisable to apply a motor with a service factor larger than 1.0 where the continuous power requirements will be greater than the normal power.

A service factor rating on a motor is to provide an increased power capacity beyond nominal nameplate capacity for occasional overload conditions. Also, the speed-torque characteristics are related to the nominal power rating and not the service factor power. When adjustable speed motor/drive systems are selected, the old service factor ratings are not useful. The supplier of the drive system will assist in selecting a thermally rated system that will satisfy the pumping operation. All inverters are equipped with thermal safety protection for both the motor and the drive so the system cannot be overloaded to minimize overheating. This is a very useful feature for many pump applications.

Efficiency Motors are designed to operate with an efficiency expressed in percent at rated voltage, frequency, and power. Efficiency is defined as

$$\text{Efficiency \%} = \frac{\text{shaft output power} \times 100}{\text{electrical input power}}$$

The efficiency of a given motor design will vary slightly from unit to unit because of manufacturing tolerances and variations in materials. For this reason, guaranteed efficiencies are usually lower than actual efficiencies. When motors are operated at reduced powers, the tendency is for the efficiency to decrease because the losses tend to be fixed.

Several other factors have an effect on motor efficiency. Increasing the applied voltage and operating a motor at its rated power will increase efficiency very slightly, whereas decreasing applied voltage will decrease the efficiency noticeably. Also, increasing the frequency will cause a very slight increase in efficiency, and decreasing the applied frequency will cause a slight decrease in efficiency.

Inverter-fed ac induction and PM or SR brushless motors are not subject to changes in their efficiencies due to changes in line voltage or frequency because the ac line voltage is rectified into a dc voltage before the regeneration of the power to the motor. The dc voltage is always reasonably constant and unaffected by changes in the line power. This of course assumes that there is sufficient voltage and power headroom in the design.

Dynamometers are used to determine efficiency for small motor ratings—up to approximately 500 hp (373 kW)—and standard methods and formulas are used for calculating efficiency for large motors. For the latter, efficiency values can vary, depending upon which “standard” procedure is used. Several suppliers market torque and power analyzers for induction motors that base their output on these formulas using current data measured from the motor. These methods are accurate enough to be acceptable. They have been reasonably verified by applying the method to smaller motors that have been tested on a

dynamometer. NEMA has established one method, but some suppliers use different methods, depending upon their national standards or established practices.

Higher efficiencies have been designed into most new motors by selecting materials and proportions that reduce losses, but such design choices usually make the motor more costly. This also includes filling the stator slots with more copper of a larger wire gage to reduce ohmic losses. These new motors designed for higher efficiencies offer improvements from 2% to as high as 7% depending upon the size and manufacturer.

Motor operating efficiency in a typical application often may not be that described by the manufacturer. Quoted efficiencies are always at rated power output, rated frequency, and rated voltage. However, it is almost universal in application that a motor is oversized for its applied load and frequently operates at other-than-normal voltage. Both of these variables can greatly reduce the efficiency of a motor. However, when a motor is inverter-driven, the efficiency of the system can be much better controlled.

Power Factor The power factor of a motor is expressed as

$$PF = 100 \cos \theta$$

where θ is the angle between voltage and current at motor terminals (leading or lagging).

The power factor at which a motor operates is dependent on the design of the motor and is established at rated voltage, frequency, and power output.

For induction motors, the power factor can never be 100% leading. A number of factors will influence the power factor of an induction motor:

| Condition | Effect on power factor |
|----------------------------|------------------------|
| Increase applied voltage | Decrease |
| Decrease applied voltage | Increase |
| Increase load | Increase |
| Decrease load | Decrease |
| Increase applied frequency | Slight increase |
| Decrease applied frequency | Slight increase |

In synchronous motors, it is usual to use two varieties of motors, the 100 (unity) and 80% leading motors. The power factor of a synchronous motor operated at rated voltage and frequency is fixed by its field excitation and its power output. At a given power output, the power factor can be adjusted over a range by adjusting the field excitation. Increasing the field excitation will cause the motor to operate at a more leading power factor, and, conversely, reducing the field excitation will make the power factor lag.

Varying the power output of a synchronous motor with a constant field excitation will vary the operating power factor. A decrease in power output will cause a more leading power factor; conversely, increasing the power output will induce operation at a lagging power factor. Consequently, to operate the motor at rated power factor with a varying output power, it is necessary to adjust the field excitation. However, this is not normally done because a synchronous motor is frequently used for improving the power factor and the more leading power factor is used to accommodate power factor improvement. When a synchronous motor is overloaded and operates at a more lagging power factor, it is not usual to increase the excitation beyond its rated excitation because of the extra heating this will develop in the motor. In this case, the more lagging power factor is simply accepted.

The power factor is not of much concern for SR and PM brushless motors driven by inverters because of the control capabilities for these systems. The PM machine exhibits the best power factor of any known motor under nearly all operating speeds and power levels except if excessive field weakening or phase advance is used.

TYPES OF CONTROLS

In order to use an electric motor to drive a pump, a means of starting and stopping the motor is required. The devices used for this purpose can be called controls. Only small—perhaps up to two or three hp (kW)—motors can be controlled with a simple on-off switch (starting from full rated line voltage). This is because when a motor is first started it produces no back EMF and will draw very high starting currents. If the load inertia is very high, the motor can overheat during the long acceleration time. In addition, the high starting current peaks can cause heavy dips in the line voltage. Therefore, for larger motors, these line voltage dips must be minimized by the use of starters. There are four basic ways to start ac induction motors:

1. Direct online starting
2. Low voltage starting
3. Rotor resistance starting
4. Low frequency starting

Other devices used to control motors such as *soft starters*, *adjustable frequency controls*, and *vector drives* are discussed along with the inverters and controls for other motor types such as dc motors, SR and PM brushless in Subsection 6.2.2.

Alternating-Current Motor Starters

MANUAL STARTERS Manual motor starters are designed to provide positive overload protection and start and stop control of single-phase and polyphase motors up to about 3 HP (2.5 kW). A single manual toggle switch or a push button switch is used for “on,” “off,” and “tripped” states. These types of starters use full line voltage applied to the motor.

MAGNETIC STARTERS Magnetic motor starters cost more and are more reliable than manual starters. They are designed to control a motor by incorporating a magnetically operated contactor to apply power to the motor terminals rather than allowing full current to pass through the contacts.

An overload relay is incorporated to protect the motor from overloading. Magnetic starters are available for reversing and nonreversing service and are also made as non-combination or combination types. The non-combination starter combines only the motor contactor and overload relay. The combination starter combines these parts along with either a circuit breaker or a fused switch to provide shortcircuit protection.

REDUCED-VOLTAGE STARTERS Reduced-voltage starters are available in several types and are basically magnetic starters with additional features to provide reduced voltage, which in turn provides for reduced motor-starting current or torque. These starters include the types discussed in the following paragraphs.

Primary-Resistor Starters Primary-resistor starters, sometimes known as *cushion-type* starters, will reduce the motor torque and starting inrush current to produce a smooth, cushioned acceleration with closed transition. Although not as efficient as other methods of reduced-voltage starting, primary-resistor starters are ideally suited to applications where reduction of starting torque is of prime consideration. A typical diagram for this type of starter is shown in Figure 20.

Autotransformer Starters Autotransformer starters are widely used reduced-voltage starters because of their efficiency and flexibility. All power taken from the line, except

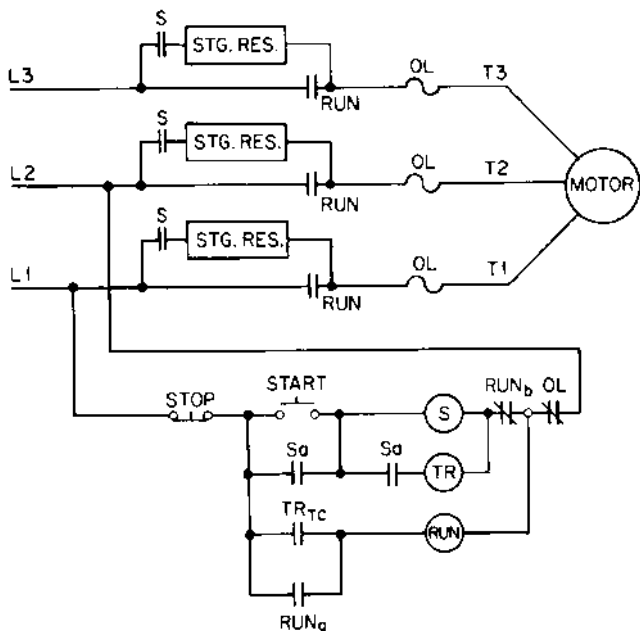

FIGURE 20 Typical primary-resistor, reduced-voltage starter wiring diagram (Westinghouse Electric)

transformer losses, is transmitted to the motor to accelerate the load. Taps on the transformer allow adjustment of the starting torque and inrush to meet the requirements of most applications. The following characteristics are produced by the three voltage taps:

| Tap, % | Starting torque, % locked torque | Line inrush, % locked current |
|--------|----------------------------------|-------------------------------|
| 50 | 25 | 28 |
| 65 | 42 | 45 |
| 80 | 64 | 67 |

A typical diagram for this type of starter is shown in Figure 21.

Part-winding starting provides convenient, economical, one-step acceleration at reduced current where the power company specifies a maximum or limits the increments of current drawn from the line. These starters can be used with standard dual-voltage motors on the lower voltage and with special part-winding motors designed for any voltage. When used with standard dual-voltage motors, it should be established that the torque produced by the first half-winding will accelerate the load sufficiently so as not to produce a second undesirable inrush when the second half-winding is connected to the line. Most motors will produce a starting torque equal to between one-half and two-thirds of NEMA standard values with half the winding energized and draw about two-thirds of normal line-current inrush. A typical diagram is shown in Figure 22.

Star-delta starters have been applied extensively to starting motors driving high-inertia loads with resulting long acceleration times. They are not, however, limited to this application. When 6 or 12 lead delta-connected motors are started star-connected, approximately 58% of full-line voltage is applied to each winding and the motor develops 33% of full-voltage starting torque and draws 33% of normal locked rotor current from the line.

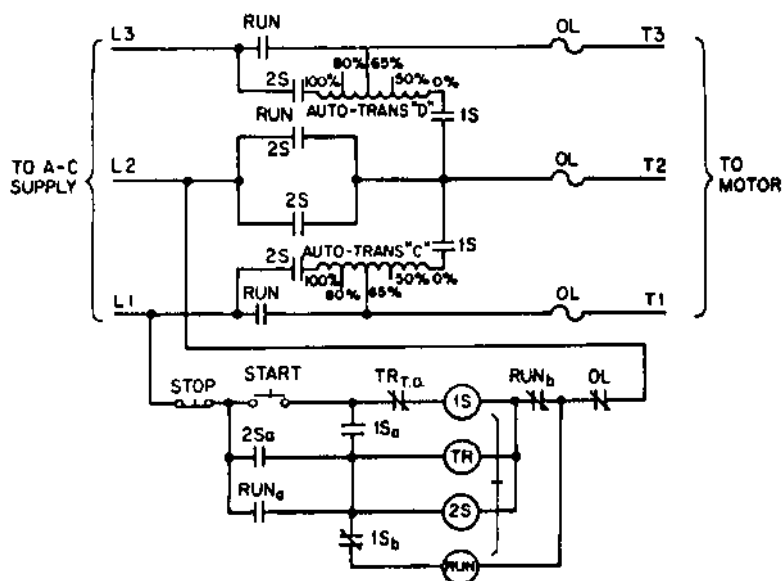

FIGURE 21 Typical autotransformer, reduced voltage starter wiring diagram (Westinghouse Electric)

FIGURE 22 Typical part-winding starter wiring diagram (Westinghouse Electric)

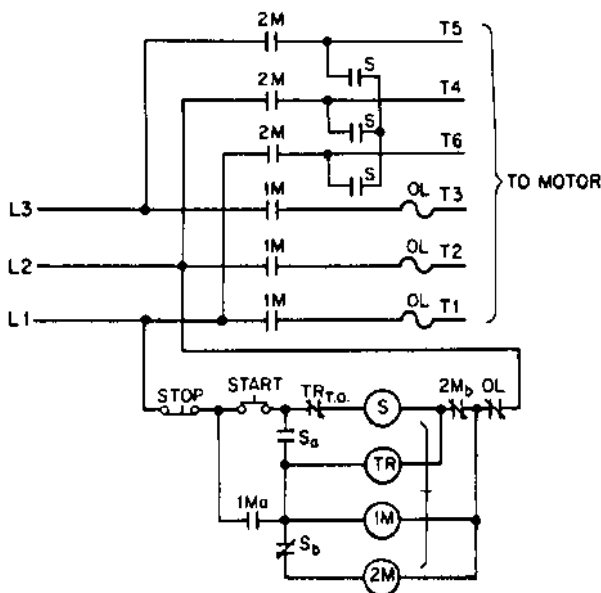

FIGURE 23 Typical star-delta, reduced-voltage starter wiring diagram (Westinghouse Electric)

When the motor has accelerated, it is reconnected for normal delta operation. A typical diagram is shown in Figure 23.

Wound Rotor Motor Starters These magnetic motor starters are used for starting, accelerating, and controlling the speed of wound-rotor motors. The primary control includes overload protection and low-voltage protection or low-voltage release, depending on the type of pilot device. Disconnect switches, circuit breakers, and reversing can be added to the primary circuit when required. Reversing starters are not designed for plugging.

The secondary circuit contains the NEMA recommended number of accelerating or running contactors and resistors to allow approximately 150% of motor full-load torque on first point of acceleration. Additional accelerating points can be added for high-inertia loads or exceptionally smooth starts. Adjustable timing relays permit field adjustment. Standard starting duty NEMA 135 resistors allow 10 s starting out of every 80 s. A typical diagram is shown in Figure 24.

Synchronous-Motor Starter Synchronous, magnetic, full-voltage starters provide reliable automatic starting of synchronous motors. They can be used whenever full-voltage starting is permissible. Automatic synchronization is provided by field relay, which assures application of the field at the proper motor speed and at a favorable angular position of stator and rotor poles. As a result, line disturbance resulting from synchronization is reduced and effective motor pull-in torque is increased. A typical diagram is shown in Figure 25.

Brushless synchronous-motor starters require special consideration inasmuch as all brushless synchronous motors are not constructed in the same way. The usual starter incorporates a low-power adjustable dc excitation source to energize and control the output of an integral shaft-connected exciter.

In addition, a pull-out relay and a timing relay are incorporated to initiate synchronization and stop the motor in event of pull-out.

Direct-Current Motor Starters Direct-current motor starters are designed to apply normal voltage to the motor field and, by means of a resistor, reduce voltage to the armature.

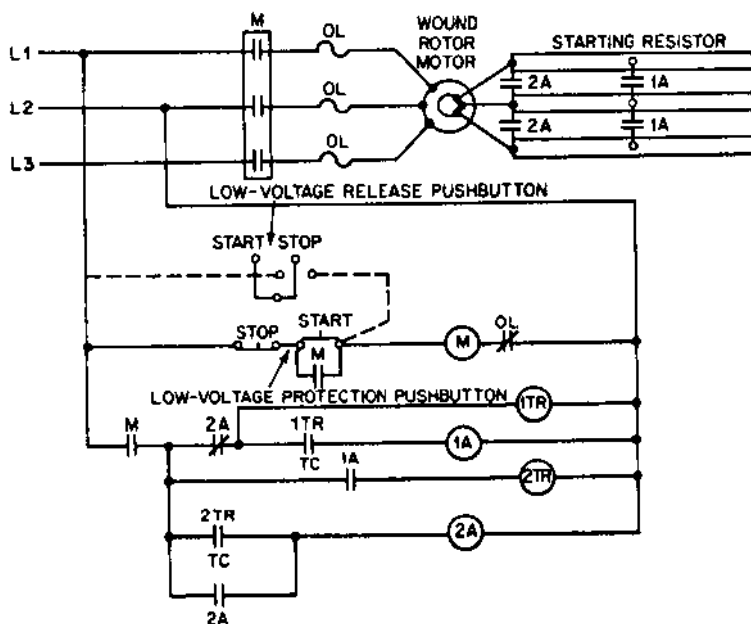

FIGURE 24 Typical wound-rotor motor starter wiring diagram (Westinghouse Electric)

FIGURE 25 Typical synchronous-motor starter wiring diagram (Westinghouse Electric)

Timing relays and contractors progressively short out the resistor until full voltage is on the armature.

If the motor is equipped with a field rheostat for field-range speed adjustment, the starter will apply the preset field voltage as adjusted by the field rheostat after full voltage is applied to the armature.

These starters incorporate a field failure relay to deenergize in the event of field failure and overload relays to protect the motor against overspeed.

The use of dc drives or SCR voltage controllers includes the facilities for all required types of starting conditions for using dc motors for pump applications. Some of these issues are covered in Subsection 6.2.2.

SEALLESS PUMP MOTORS

Various centrifugal pump designs are available that require no shaft sealing; that is, no packing or mechanical seal. These pumps are completely leakproof, and some are submersible. Such pumps are used when leakage cannot be tolerated or when pumping conditions such as pressure and/or temperature make conventional sealing difficult, if not impossible.

The shaft seal is eliminated by joining the pump and motor housings together to create a single leakproof unit. The impeller and motor rotor are mounted on a single shaft. Most designs permit the pumped liquid to circulate through the motor rotor and motor bearings. However, there are designs where either circulation is also through the stator or the stator is sealed and filled with dielectric oil. See Subsection 2.2.7.2.

Another popular method used for smaller pumps is to separate the pump shaft completely from the motor shaft. A permanent magnet coupling is provided to transmit the motor torque to the pump shaft through a nonmagnetic shell or section of the pump housing. The pump and motor can be integrated in these designs. See Subsection 6.3.2 and 2.2.7.1.

Figure 26 classifies various motor designs and references other places in the handbook where the special features and applications of these units are described in more detail.

6.1.2 STEAM TURBINES

WALLACE L. BERGERON

DEFINITIONS

“A steam turbine may be defined as a form of heat engine in which the energy of the steam is transformed into kinetic energy by means of expansion through nozzles, and the kinetic energy of the resulting jet is in turn converted into force doing work on rings of blading mounted on a rotating part.”¹

This definition may be restated:

“A steam turbine is a prime mover which converts the thermal energy of steam directly into mechanical energy of rotation.”²

REASONS FOR USING STEAM TURBINES

Steam turbines are used to drive pumps for a variety of reasons:

1. The economical generation of steam often requires boiler steam pressures and temperatures that are considerably in excess of those at which the steam is utilized. Steam may also be used at two or more pressure levels in the same plant. Pressure reduction can be accomplished through valves, pressure-reducing stations, or use of a steam turbine.

Pressure reduction by using a steam turbine and thereby developing power to drive a pump permits lower utility costs. The incremental increase in steam flow and consequently in fuel costs for the same lower pressure steam heating load is in most instances less than the cost of purchased power for a motor-driven pump.

2. A pump driven by a steam turbine may be operated over a wide speed range, utilizing the turbine governor system or a separately controlled valve in the turbine or in the steam line to the turbine. Operation at variable speeds is an inherent characteristic

of steam turbines and does not require the use of special speed-changing devices, as is the case with other prime movers.

The overall efficiency of the turbine and pump unit can be optimized by operating at reduced speeds and at the resultant reduced power ratings. Pump performance can be controlled by reducing the speed of the pump rather than throttling it. Although the turbine efficiency normally declines when operating at a reduced speed, the steam flow will still be less than when the pump is throttled.

Operation at reduced power but at constant speed is also permitted by the speed governor, which throttles the steam to the nozzles as the power is reduced. Efficiency may be improved by equipping the turbine with auxiliary steam valves that are closed for reduced power operation. Closing these valves reduces the available nozzle area and reduces the pressure drop across the governor valve.

When the turbine is operated with the auxiliary steam valve closed, the steam flow will approximate that for the same turbine designed for the reduced rating.

3. The use of a steam turbine driver permits the driven pump to operate essentially independent of the electric power or distribution system. The steam turbine is not affected by electric power stoppages or interruptions and is therefore ideal for critical pumping operations.
4. A turbine may be used as a secondary driver for a pump; it may also drive an independent standby or emergency pump. The particular plant design may not afford sufficient steam for the pump to be normally driven by the steam turbine. However, in the event of an electric power failure or power system disturbance, a steam turbine may be employed as a dual drive or to drive a separate pump to assure continued operation of the plant until the electric power system is again operable.
5. The steam turbine controls—governor system and overspeed trip system—are inherently sparkproof. Consequently, steam turbines can be readily applied to drive centrifugal pumps in a wide variety of hazardous atmospheres without entailing additional cost for explosionproof or sparkproof construction.
6. Steam turbines can normally be readily altered to accommodate an increase in rating for increased pump output or for new pump applications. This inherent flexibility of a steam turbine also permits it to be readily altered to accommodate changes in the initial steam pressure and temperature and in the exhaust steam pressure at which the turbine operates.
7. Steam turbines have a starting, or breakaway, torque of approximately 150 to 180% of the rated torque. Additional starting torque can be readily furnished by designing the turbine for the additional required steam flow—and without reducing the efficiency at the normal operating rating by using an auxiliary steam valve. The additional starting torque can often be obtained without increasing the turbine frame size.
8. Steam turbines can be used to drive all types of pumps.
9. Steam turbines are inherently self-limiting with respect to the power developed. Special protective devices do not have to be furnished to prevent damage to the turbine because of overload conditions. The maximum power that can be developed by a turbine is a function of the flow areas provided in the design of the nozzle ring and governor valve. Application of a load greater than that which can be developed by the turbine causes the turbine to slow down to a speed at which the torque generated by the turbine matches that required by the pump.
10. When the pump application requires the driver to be designed with excess power or to permit operation of the pump “at the end of the curve,” the steam turbine can be designed for the corresponding rating without reducing the turbine efficiency when operating at the normal rating. Closing an auxiliary steam valve furnished for operation at the normal rating preserves efficiency because the turbine governor valve is not throttling to obtain the power rating.
11. With respect to the operation of the various types of pump drivers and their supporting systems, steam turbines afford minimum maintenance, low vibration, and a quiet installation.

TYPES OF STEAM TURBINES

Single-Stage Turbines A single-stage steam turbine is one in which the conversion of the kinetic energy to mechanical work occurs with a single expansion of the steam in the turbine—from inlet steam pressure to exhaust steam pressure.

A single-stage turbine may have one or more rows of rotating buckets that absorb the velocity energy of the steam resulting from the single expansion of the steam.

Single-stage turbines are available in wheel diameters of 9 to 28 in (22 to 71 cm). The overall efficiency of a turbine for a particular operating speed and steam conditions is normally dependent on the wheel diameter. The efficiency will generally increase with an increase in wheel size, and therefore the steam rate will be less (for the more usual speeds and steam conditions).

The larger-wheel-diameter steam turbines can be furnished with more nozzles to provide increased steam flow capacity and consequently greater power capabilities. The larger-wheel-diameter turbines are therefore furnished with larger steam connections, valves, shafts, bearings, and so on. Consequently the size of the turbine will generally increase with increases in power rating.

Multiple-Stage Turbines A multiple-stage turbine is one in which the conversion of the energy occurs with two or more expansions of the steam in the turbine. The number of stages (steam expansions) is a function of three basic parameters: thermodynamics, mechanical design, and cost. The thermodynamic considerations include the available energy and speed. The mechanical considerations include speed, steam pressure, steam temperature, and so on, most of which are material limits. Cost considerations include the number, type, and size of the stages; the number of governor-controlled valves; the cost of steam; and the number of years used as a basis for the cost evaluation.

The two factors generally used in selecting multistage turbines are initial cost and steam rate. Because these two factors are a function of the total number of stages, the application becomes a factor of stage selection. The initial cost increases with the number of stages, but the steam rate generally improves.

Multiple-stage turbines are normally used to drive pumps when the cost of steam or the available supply of steam requires turbine efficiencies greater than these available with a single-stage turbine, or when the steam flow required to develop the desired rating exceeds the capability of single-stage turbines.

Multiple-stage turbines can be furnished with a single or multiple governor valves. A single governor valve is often of the same design whether used in a single-stage or multiple-stage turbine and generally has the same maximum steam flow, pressure, and temperature parameters. Multiple valves are used when the parameters for a single valve are exceeded or to obtain improved efficiency, particularly at reduced power outputs.

Shaft Orientation Some steam turbines, particularly single-stage turbines, can be furnished with vertical downward shaft extensions. The application of such turbines can require considerable coordination between the pump and the turbine manufacturer to assure an adequate thrust bearing in the turbine, shaft length and details, mounting flange dimensions, and even shaft runout.

Vertical shaft pumps are frequently driven by horizontal turbines through a right-angle speed-reduction gear unit.

Direct-Connected and Geared Turbines Steam turbines can be directly connected to the pump shaft so the turbine operates at the pump speed or can drive the pump through a speed-reduction (and even speed-increase) gear unit, in order to permit the turbine to operate at a more efficient speed.

Turbine Stages The two types of turbine stages are impulse and reaction. The turbines discussed in this subsection employ impulse stages because steam turbines driving pumps normally have impulse-type stages.

In the ideal impulse stage, the steam expands only in the fixed nozzles and the kinetic energy is transferred to the rotating buckets as the steam impinges on the buckets while

flowing through the passages between them. The steam pressure is constant, and the steam velocity relative to the bucket decreases in the bucket passages.

In a reaction stage, the steam expands in both the fixed nozzles and the rotating buckets. The kinetic energy is transferred to the rotating buckets by the expansion of the steam in the passages between the buckets. The steam pressure decreases as the steam velocity relative to the buckets increases in the bucket passages.

In an impulse stage, the steam can exert an axial force on the buckets as it flows through the blade passages. Although this force is usually referred to as a reaction, the use of the term does not imply a reaction-type stage.

The larger buckets used in the last stages of an impulse-type multistage turbine can be of a free-vortex design—twisted and tapered. Such a bucket is ideally subjected to a nearly pure impulse force at its root and a nearly pure reaction force at its tip, but, in reality, this bucket is a high reaction-design bucket compared with a normal impulse-stage bucket. A steam turbine stage with such a bucket design is still referred to as an impulse stage because the primary conversion of kinetic energy is by a reduction rather than an increase in relative steam velocity.

A reaction turbine has more stages than an impulse turbine for the same application because of the small amount of kinetic energy absorbed per stage, and requires a larger thrust bearing or a balancing piston because of the pressure drop across the moving blades. The small pressure drop per stage and the pressure drop across the moving blades require that the steam-leakage losses be minimized by elaborate sealing between the tips of the nozzle blades and the rotor, and the tips of the moving blades and the casing.

The small pressure differential across the rotating blades of an impulse stage results in smaller thrust bearings and no close blade-tip clearances. Consequently impulse turbines can be started more quickly without thermal-expansion damage, and their stage efficiencies remain relatively constant over the life of the turbine.

CONSTRUCTION DETAILS

Component Parts The main components of a single-stage steam turbine are shown in Figure 1.

FIGURE 1 Component parts of steam turbines (Elliott)

Function and Operation—Single-Stage Turbine The *steam* chest and the *casing* contain the steam furnished to the turbine, being connected to the higher-pressure steam supply line and the lower-pressure steam exhaust line, respectively. The steam chest, which is connected to the casing, houses the governor valve and the overspeed trip valve. The casing contains the rotor and the nozzles through which the steam is expanded and directed against the rotating buckets.

The *rotor* consists of the shaft and disk assemblies with buckets. The shaft extends beyond the casing and through the bearing cases. One end of the shaft is used for coupling to the driven pump. The other end serves the speed governor and the overspeed trip systems.

The *bearing cases* support the rotor and the assembled casing and steam chest. The bearing cases contain the journal bearings and the rotating oil seals, which prevent outward oil leakage and the entrance of water, dust, and steam. The steam end bearing case also contains the rotor positioning bearing and the rotating components of the overspeed trip system. An extension of the steam end bearing housing encloses the rotating components of the speed governor system.

The *casing sealing glands* seal the casing and the shaft with spring-backed segmented carbon rings (supplemented by a spring-backed labyrinth section for the higher exhaust steam pressures).

The *governor system* commonly consists of spring-opposed rotating weights, a steam valve, and an interconnecting linkage or servomotor system. Changes in the turbine inlet and exhaust steam conditions, and the power required by the pump will cause the turbine speed to change. The change in speed results in a repositioning of the rotating governor weights and subsequently of the governor valve.

The *overspeed trip system* usually consists of a spring-loaded pin or weight mounted in the turbine shaft or on a collar, a quick-closing valve that is separate from the governor valve, and interconnecting linkage. The centrifugal force created by rotation of the pin in the turbine shaft exceeds the spring loading at a preset speed. The resultant movement of the trip pin causes knife edges in the linkage to separate and permit the spring-loaded trip valve to close.

The trip valve may be closed by disengaging the knife edges manually, by an electric or pneumatic signal, by low oil pressure, or by high turbine exhaust steam pressure.

The two usual types of lubrication systems are oil-ring and pressure. The *oil-ring* lubrication system employs an oil ring(s) that rotates on the shaft with the lower portion submerged in the oil contained in the bearing case. The rotating ring(s) transfers oil from the oil reservoir to the turbine shaft journal bearing and rotor-locating bearing. The oil in the bearing case reservoirs is cooled by water flowing in cooling water chambers or tubular heat exchangers.

A *pressure* lubrication system consists of an oil pump driven from the turbine shaft, an oil reservoir, a tubular oil cooler, an oil filter, and interconnecting piping. Oil is supplied to the bearing cases under pressure. The oil rings may be retained in this system to provide oil to the bearings during startup and shutdown when the operating speed and bearing design permit.

Typical sectional drawings are shown in Figures 2, 3, and 4.

GOVERNORS AND CONTROLS

Governor systems are typically speed-sensitive control systems. The turbine speed is controlled by varying the steam flow through the turbine by positioning the governor valve. Variations in the power required by the pump and changes in steam inlet or exhaust conditions alter the speed of the turbine, causing the governor system to respond to correct the operating speed.

Control systems, unlike governor systems, are not directly speed-sensitive but respond to changes in pump or pump-system pressures and then reposition the turbine “governor” valve to maintain the preset pressure. Consequently, changes in turbine steam conditions or in the power required by the pump result in a repositioning of the turbine governor

FIGURE 2 Section of single-stage turbine and governor system (Elliott)

FIGURE 3 Typical turbine overspeed trip arrangement (Dresser-Rand).

valve or of a separate steam valve only after the pressure being sensed by the controller has changed.

Even when a control system is furnished, a speed governor is also normally furnished. The speed governor is set for a speed slightly higher than the desired operating speed in order to function as a pre-emergency governor; that is, prevent the turbine from reaching the trip speed when the controller causes the turbine to operate at a speed above rated speed.

Governor systems are defined by their performance as follows:²

| Class of governor system | Speed range, % (as specified) | Maximum speed regulation, % | Maximum speed variation, %, \pm | Maximum speed rise, % |
|--------------------------|-------------------------------|-----------------------------|-----------------------------------|-----------------------|
| A | 10–65 | 10 | 0.75 | 13 |
| B | 10–80 | 6 | 0.50 | 7 |
| C | 10–80 | 4 | 0.25 | 7 |
| D | 10–90 | 0.50 | 0.25 | 7 |

Speed range is the percentage below rated speed for which the governor speed setting may be adjusted. For example, a turbine with 4000 rpm rated speed and a governor system having a 30% range can be operated at a minimum speed of 2800 rpm:

$$4000 - \frac{30 \times 4000}{100} = 2800$$

FIGURE 4 Section of multistage turbine (Elliot)

If the speed range had been specified as plus 5% and minus 25%, for example, the maximum and minimum speeds would be 4200 and 3000 rpm.

Steady-state speed regulation is the change in speed required for the governor system to close the governor valve when the load is gradually reduced from rated load to no load with turbine steam conditions constant. Regulation is always expressed as a percentage of rated speed and calculated as follows:

$$\frac{\text{No-load speed} - \text{rated speed}}{\text{Rated speed}} \times 100 = \% \text{ regulation}$$

Therefore

$$\text{No-load speed} = \text{rated speed} \left(1 + \frac{\% \text{ regulation}}{100} \right)$$

A turbine with 4000 rpm rated speed and equipped with a NEMA A speed governor system would have 4400 rpm maximum no-load speed:

$$4000 \times \left(1 + \frac{10}{100} \right) = 4400 \text{ rpm}$$

Consequently, whenever the turbine is developing less than rated power, the operating speed will be greater than rated speed, as required for the governor system to reposition the governor valve.

Speed variation, expressed as a percentage, is the total magnitude of the fluctuations from the set speed permitted by the governor system when the turbine is normally operating at rated speed, power, and steam conditions. This is the “insensitivity” of the governor system. The speed variation equation is

$$\frac{\text{Maximum speed} - \text{minimum speed}}{\text{Rated speed} \times 2} \times 100 = \pm \% \text{ speed variation}$$

A turbine with 4000 rpm rated speed and NEMA A governor system would have ± 30 rpm maximum speed variation:

$$4000 \times \frac{\pm 0.75}{100} = \pm 30 \text{ rpm}$$

Maximum speed rise represents the momentary increase in speed when the load is suddenly reduced from rated power to no-load power with the pump still coupled to the turbine shaft. Shortly after the sudden loss of load, the governor system will cause the turbine speed to be reduced to the no-load speed.

Maximum speed rise is also expressed as a percentage of rated speed and calculated as follows:

$$\frac{\text{Maximum speed} - \text{rated speed}}{\text{Rated speed}} \times 100 = \% \text{ speed rise}$$

Therefore

$$\text{Maximum speed} = \text{rated speed} + \frac{\text{rated speed} \times \% \text{ speed rise}}{100}$$

A turbine with 4000 rpm rated speed and equipped with a NEMA A governor will have a maximum speed rise to

$$4000 + \frac{4000 \times 13}{100} = 4520 \text{ rpm}$$

The setting of the *overspeed trip* is a function of the maximum speed rise of the governor system—it must be higher than the maximum speed rise. The recommended settings are

| Class of governor system | Overspeed trip setting, (% of rated speed) |
|--------------------------|--|
| A | 115 |
| B | 110 |
| C | 110 |
| D | 110 |

The overspeed trip system for a turbine with 4000 rpm rated speed and equipped with a NEMA A governor is set for operation at

$$4000 \times \frac{115}{100} = 4600 \text{ rpm}$$

The speed-sensitive portion of the speed governor system is usually a set of spring-loaded rotating weights. Movement of the weights caused by a change in turbine speed positions the governor valve through a suitable linkage.

The speed-sensitive element can also be other devices that are speed-responsive, such as a positive displacement oil pump, electric generator, or a magnetic impulse signal generator.

The rotating-weight governor system is a direct-acting type and is classified as a NEMA A governor. *Direct-acting* designates a governor system in which the speed-sensitive element also provides the power for positioning the governor valve.

The NEMA B, C, and D governor systems have speed-sensitive elements that position the governor valve through a relay or servomotor system instead of actuating the valve directly. The speed-sensitive element can therefore be more precise and sensitive, as required for the improved governor system performance.

Electronic governors with pneumatic/hydraulic actuators are also available that offer more control, flexibility, and speed adjustment as well as other operating modes.

THEORY

A steam turbine develops mechanical work by converting to work the available heat energy in the steam expansion. Heat and mechanical work, being two forms of energy, can be converted from one to the other.

The heat energy is converted in two steps. The steam expands in nozzles and discharges at a high velocity, converting the available heat energy to velocity (kinetic) energy. The high-velocity steam strikes moving blades, converting the velocity energy to work. Because the total heat energy available in the steam is converted to velocity (kinetic) energy, the magnitude of the steam velocity is dependent upon the available energy.

The mechanical work that is developed in the turbine by the high-velocity steam striking the buckets is a function of the speed of the buckets. Maximum work occurs when the bucket velocity is approximately one-half the steam jet velocity for an impulse stage and one-fourth the steam jet velocity for a velocity-compounded impulse stage. Although the steam jet velocity is fixed by the available heat energy, the bucket velocity is fixed by the speed of the turbine and the diameter of the turbine wheel on which the buckets are mounted. The work developed, or the efficiency of the turbine, ignoring losses in the turbine, is therefore determined by the size of the turbine and the turbine (pump) speed for a fixed amount of available heat energy.

The most common single-stage turbine is the velocity-compounded (Curtis) type. The complete expansion from inlet to exhaust pressure occurs in one step. The Curtis stage,

FIGURE 5 Velocity-compounded stages: (a) Curtis stage; steam flows once through moving buckets; (b) re-entry stage; steam flows twice through moving buckets; (c) re-entry stage; steam flows three times through moving buckets (reprinted with permission from *Power*, June 1962)

with two rows of rotating buckets, and two re-entry-type velocity-compounded stages are illustrated in Figure 5.

Single-stage turbines are available with a wide range of efficiencies because they are manufactured with a variety of wheel diameters: 9 to 28 in (22 to 71 cm).

Multistage turbines are manufactured with a more limited variety of wheel sizes. The efficiency of multistage turbines is varied primarily by varying the number of stages. When the total available energy of the steam results in a steam velocity greater than twice the bucket velocity (using convenient wheel sizes), a multistage turbine will be more efficient. In a multistage turbine, the total steam expansion is divided among the various impulse stages to produce the desired steam velocity for each row of buckets.

A steam turbine is normally evaluated using *steam rate*—the amount of steam required by the turbine to produce the specified power per hour at the specified speed—rather than *efficiency*. The steam rate is a direct function of the turbine efficiency.

The steam consumption can be expressed either as steam rate, pounds of steam per horsepower-hour (kilograms per kilowatt-hour) or as steam flow, pounds of steam per hour (kilograms per hour). The higher the efficiency, the lower the steam rate or steam flow, and vice versa.

The total available energy of the steam is that available from an isentropic expansion. For given initial steam pressure and temperature and exhaust pressure, the available energy in British thermal units per pound (kilojoules per kilogram) of steam can be obtained from the tables or the Mollier chart in Reference 3.

The available energy can be converted to power units and expressed as the theoretical steam rate—pounds per horsepower-hour or pounds per kilowatt-hour (kilograms per kilowatt-hour). The theoretical steam rate is the steam rate for a 100% efficient turbine and therefore can be used more conveniently than energy in British thermal units per pound (kilojoules per kilogram) for the calculation of turbine steam rates. Theoretical steam rates can be obtained directly from theoretical steam rate tables (ASME) or from the polar Mollier chart (Elliott Company).

The actual steam rate for a turbine is greater than the theoretical steam rate because of the losses that occur in the turbine when the available energy is converted to mechanical work and because of the ratio of the steam velocity to bucket velocity. The energy remaining in the steam exhausting from the turbine is greater than that after an isentropic expansion, as illustrated in Mollier diagram shown in Figure 6, where

- 1 = energy in steam at initial steam pressure and temperature
- 2 = energy in steam at exhaust pressure for an isentropic expansion
- 3 = actual energy in steam at exhaust pressure

FIGURE 6 Mollier diagram with energy losses

The efficiency of the turbine is

$$\frac{h_1 - h_3}{h_1 - h_2} \quad \text{or} \quad \frac{\text{theoretical steam rate}}{\text{actual steam rate}}$$

The governor and trip valve pressure drop losses are a function of the sizes of these two valves and the steam flow. The governor valve pressure drop will vary more than the trip valve pressure drop because of changes in valve position with power required by the driven pump, speed variations, and changes in inlet and exhaust steam conditions.

The nozzle loss is due to friction in the nozzles as the steam expands. The efficiency of the nozzles is a function of the ratio of the actual and ideal exit steam velocities squared. The efficiency is usually between 95 and 99%.

The windage and disk friction losses are due to the friction between the stream and the disks and the blades fanning the steam. This loss varies inversely with the specific volume of the steam, increases with exhaust pressure, and increases with the diameter of the wheel and the length of the blades.

The use of a larger-diameter wheel may increase the efficiency, but the windage and disk friction losses will reduce the improvement and may even cause a net loss in overall efficiency.

The exhaust losses represent the kinetic energy remaining in the steam as a result of the velocity of the steam leaving the bucket and the pressure drop in the steam as it passes out the exhaust connection.

The energy conversion loss is due to the nonideal conversion of the steam velocity energy to mechanical work in the buckets as a function of the steam velocity and bucket velocity, plus nonideal nozzle and bucket angles, friction in the system, and so on.

The performance that can be expected from a single-stage Curtis-type turbine may be obtained from Figures 7, 8, and 9, and Table 1 after determining the theoretical steam rate.

$$\text{Steam rate} = \frac{\text{base steam rate}}{\text{superheat correction factor}} \times \frac{\text{power} + \text{power loss}}{\text{power}}$$

To obtain superheat, subtract temperature given in Table 1 from total initial temperature.

FIGURE 7 Base steam rates (Elliott)

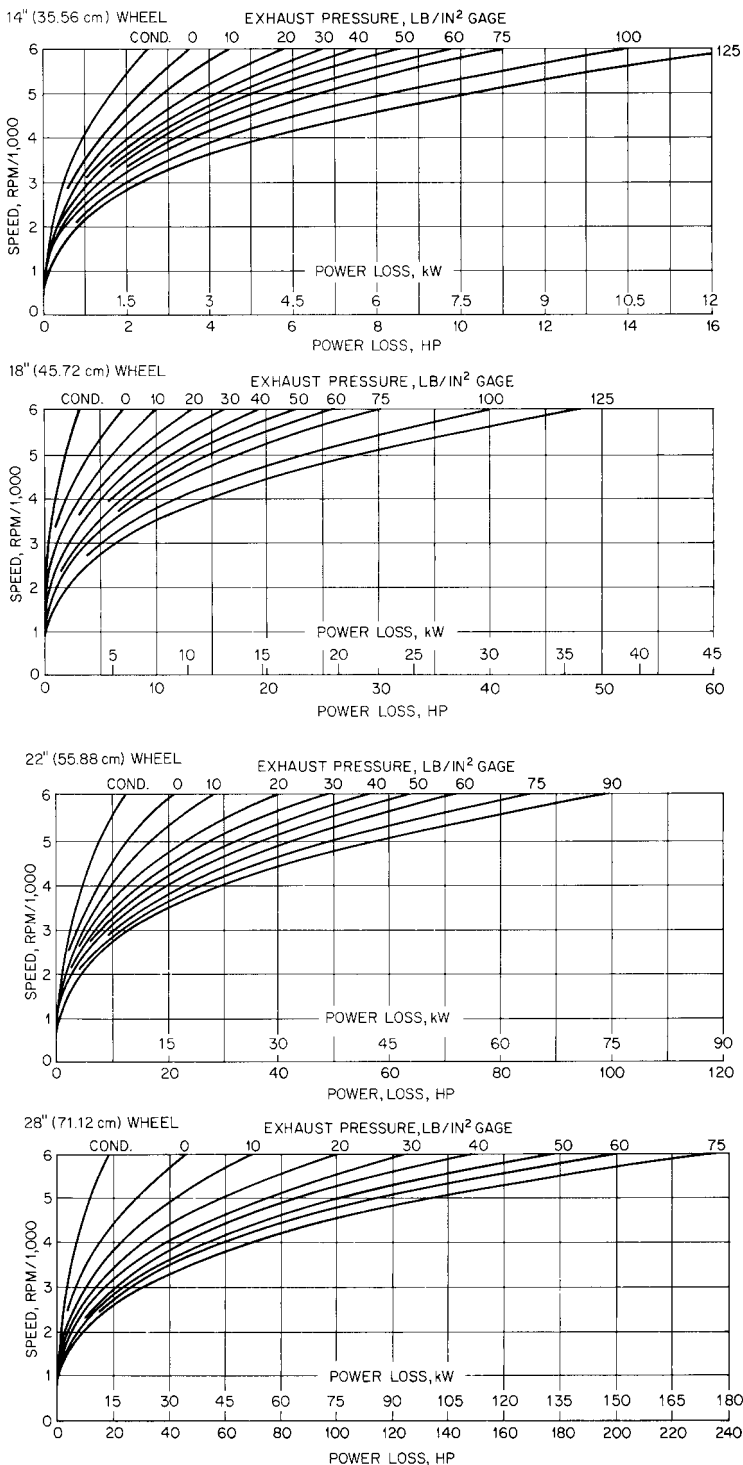

FIGURE 8 Power loss (lb/in² × 6.895 = kPa) (Elliott)

FIGURE 9 Superheat correction factor (Elliott)

SAMPLE CALCULATION

STEAM CONDITIONS 250 lb/in² (1724 kPa) gage inlet, 575°F (302°C) inlet, and 50 lb/in² (345 kPa) gage exhaust.

DESIGN CONDITIONS turbine to develop 500 hp (373 kW) at 4000 rpm.

1. Theoretical steam rate = 26.07 lb/kWh (11.82 kg/kWh)
2. Base steam rate for 28-in (71.12-cm) wheel (Figure 7) = 36 lb/hp · h (22 kg/kWh)
3. Power loss for 28-in (71.12-cm) wheel (Figure 8) = 55 hp (41 kW)
4. Temperature of dry and saturated inlet steam (Table 1) = 406°F (208°C)
5. Superheat (Table 1) = 575 – 406 = 169Δ°F (302 – 208 = 94Δ°C)
6. Superheat corrections factor (Figure 9) = 1.052
7. Steam rate =

$$\text{In USCS units} \quad \frac{36}{1.052} \times \frac{500 + 55}{500} = 38.0 \text{ lb/hp} \cdot \text{h}$$

$$\text{In SI units} \quad \frac{21.89}{1.052} \times \frac{373 + 41}{373} = 23.1 \text{ kg/kWh}$$

The ability of a particular size turbine to develop the required power is determined primarily by

1. The flow capacity of the inlet and exhaust connection from Figures 10 and 11, where steam flow = power × steam rate
2. The flow capacity of the nozzles available in a particular turbine (the number and size of the nozzles vary considerably with each design of turbine manufactured, and thus a meaningful plot cannot be included here).

TABLE 1 Temperature of dry and saturated steam

| Lb/in ² gage | Saturation temp., °F | Lb/in ² gage | Saturation temp., °F | Lb/in ² gage | Saturation temp., °F | Lb/in ² gage | Saturation temp., °F |
|----------------------------|-------------------------|----------------------------|-------------------------|----------------------------|-------------------------|----------------------------|-------------------------|
| 0 | 213 | 150 | 366 | 300 | 422 | 450 | 460 |
| 5 | 228 | 155 | 368 | 305 | 423 | 455 | 461 |

| 130 | 356 | 280 | 416 | 430 | 455 | 660 | 499 |
| 135 | 358 | 285 | 417 | 435 | 456 | 670 | 501 |
| 140 | 361 | 290 | 419 | 440 | 457 | 680 | 502 |
| 145 | 364 | 295 | 420 | 445 | 458 | 690 | 504 |

To obtain superheat, subtract temperature given above from total initial temperature. Pressure in kPa = $6.895 \times \text{lb/in}^2$. Temperature in °C = $(^\circ\text{F} - 32) \div 1.8$.

EVALUATION OF COSTS

The economical selection of a turbine considers the initial cost of the turbine and the operating costs. A lower-steam-rate (more efficient) turbine generally has a higher initial cost than a turbine with a higher steam rate. The operating costs are the cost of the steam for the number of years upon which the evaluation is to be based:

$$\text{Total cost} = \text{initial cost} + \left(\text{power} \times \frac{\text{steam}}{\text{rate}} \times \frac{\text{steam}}{\text{cost}} \times \frac{\text{operating hours}}{\text{per year}} \times \frac{\text{number}}{\text{of years}} \right)$$

The cost of installation—foundation, steam piping, and cooling water service (also electric service if required)—is not normally considered unless there are significant differences between the turbines: single-stage versus multistage, direct-connected versus turbine and gear, vertical turbine versus horizontal turbine with a right-angle gear, and so on.

The economical selection of a steam turbine versus an electric motor, diesel engine, gas engine, gas turbine, and so on, must include an evaluation of all installation costs, costs of

6.1.3 ENGINES

F. J. GUNTHER

ENGINE SELECTION AND APPLICATION

The internal combustion engine is used extensively as a driver for centrifugal and displacement pumps. Depending on the application, the engine fuel may be gasoline, natural gas, liquid petroleum gas (LPG), sewage gas, or diesel fuel. It may be either liquid- or air-cooled.

Basic Design Variations The basic design of the engine may vary. The cylinder block construction is vertical or horizontal, in-line or V-type. The number of cylinders ranges from 1 to 20. The engine cycle is either four (one power stroke in two revolutions of the crankshaft) or two (one power stroke in one revolution of the crankshaft). The combustion chamber and cylinder head design are classed as L-head (valves in the cylinder block) or valve-in head. In the diesel engine, the combustion chamber may be of the precombustion chamber design, where an ante chamber is used to initiate combustion, or of the direct injection design, where the fuel is injected directly into the cylinder. The piston design action may be vertical, horizontal, at an angle as in the V-type engine, or opposed piston (two pistons operating in the same cylinder).

Power Ratings The power range of engines in current production, depending on displacement, number of cylinders, and speed, is as follows:

1. Air-cooled gasoline, natural gas, and diesel: 1.0 to 75 hp (0.75 to 56 kW)
2. Liquid-cooled gasoline: 10 to 300 hp (75 to 224 kW)
3. Liquid-cooled natural gas, LPG, and sewage gas: 10 to 15,000 hp (75 to 11,200 kW)
4. Liquid-cooled diesel: 10 to 50,000 hp (75 to 37,300 kW)
5. Dual fuel, natural gas, LPG, and diesel: 150 to 25,000 hp (112 to 18,700 kW)

FIGURE 1 Natural gas engine driving a horizontal water pump for Winnipeg, Canada, water utility (Waukesha Motor)

FIGURE 2 Diesel engine driving pumps for flood-control station in Seattle (Waukesha Motor)

Typical engine driver applications are represented in Figures 1 and 2.

The rating of the internal combustion engine is the most important consideration in making the proper selection. The general practice is to rate engines according to the severity of the duty to be performed. The most common rating classifications are maximum, standby or intermittent, and continuous.

The maximum output is based on dynamometer tests that are corrected to standard atmospheric conditions for temperature and barometric pressure. In applications, this power rating is reduced by accessories such as cooling fans, air cleaners, and starting systems.

Standby, or intermittent, and continuous ratings are arrived at by applying a percentage factor to the net maximum power rating. For example, 75 to 80% is used for continuous and 90% for intermittent.

Duty cycle is a term used to describe the load pattern imposed on the engine. If the load factor (ratio of average load to maximum capabilities) is low, we call the duty cycle "light," but if it is high, we classify the cycle "heavy." Continuous, or heavy-duty, service is generally considered to be 24 h/day, with little variation in load or speed. Intermittent service is classified as duty where an engine is called upon to operate in emergencies or at reduced loads at frequent intervals.

In analyzing power problems when selecting a proper engine, certain terms are used in the industry:

DISPLACEMENT The displacement in cubic inches (cubic centimeters) of an engine cylinder is

In USCS units, $D = \text{bore (in)}^2 \times 0.7854 \times \text{stroke (in)} \times \text{no. of cylinders}$

In SI units $D = \text{bore (cm)}^2 \times 0.7854 \times \text{stroke (cm)} \times \text{no. of cylinders}$

Torque The twisting effort of the engine in pound-feet (Newton-meters) is

In USCS units $T = 5252 \times \frac{\text{bhp}}{\text{rpm}}$

In SI units $T = 9545 \times \frac{\text{bkW}}{\text{rpm}}$

ENGINE POWER This is a measure of the theoretical characteristics of an engine. Brake horsepower (bkW) is the measurable power after the deduction for frictional losses:

In USCS units $\text{bhp} = T \times \frac{\text{rpm}}{5252}$

In SI units $\text{bkW} = T \times \frac{\text{rpm}}{9545}$

BRAKE MEAN EFFECTIVE PRESSURE The average cylinder pressure to give a resultant torque at the flywheel in pounds per square inch (kilopascals)

In USCS units $\text{bmep} = \frac{792,000 \times \text{bhp}}{\text{rpm} \times D} \text{ (four-cycle)}$

$$\text{bmep} = \frac{396,000 \times \text{bhp}}{\text{rpm} \times D} \text{ (two cycle)}$$

In SI units $\text{bmep} = \frac{120 \times 10^6 \times \text{bkW}}{\text{rpm} \times D} \text{ (four-cycle)}$

$$\text{bmep} = \frac{60 \times 10^6 \times \text{bkW}}{\text{rpm} \times D} \text{ (two cycle)}$$

PISTON SPEED At a given speed, the average velocity of piston in feet per minute (centimeters per minute) is

In USCS units $\text{Piston speed} = \text{stroke (in)} \times 2 \times \frac{\text{rpm}}{12}$

In SI units $\text{Piston speed} = \text{stroke (cm)} \times 2 \times \frac{\text{rpm}}{6000}$

In selecting an engine for a particular application, the following variables should be considered:

- Altitude
- Ambient air temperature

- Rotation and speed
- Bmep and piston speed
- Maintenance
- Type of fuel
- Operating atmosphere (dust and dirt)
- Vibrations and torsionals
- Engine pollutants

The observed power is that produced by an engine at the existing altitude and temperature. All engine manufacturers publish power ratings corrected to certain conditions; for conditions other than these, it is necessary to correct by applying a percentage factor for altitude and temperature. Generally this is $3\frac{1}{2}\%$ per thousand feet (305 m) above sea level and 1% for every 10°F (5.6°C) above 60°F (50.4°C). In a turbocharged engine, there is no established standard and the engine manufacturer should be consulted.

The basic rotation of engines in current production is counterclockwise when viewed from the flywheel end of the engine, although many of the larger engines are available in both counterclockwise and clockwise rotation. The speed of the engine is generally fixed by the equipment being driven. Through the use of speed-increasing or -reducing gear boxes, the proper engine for a given application may be selected. A gear box may also be used to correct a rotation problem.

Speed ranges for engines generally fall into three categories:

- High—above 1500 rpm
- Medium—700 to 1500 rpm
- Low—below 700 rpm

High-speed engines generally offer weight and size advantages as well as cost savings and thus are used for standby applications. On the other hand, medium- or low-speed engines, although heavier and larger, offer a gain in service life and lower maintenance costs.

The speed flexibility of an engine drive is important when the engine is to be used to drive a pump that must move variable quantities of liquid. The engine speed may be changed very simply either manually or through the use of liquid or pressure controls.

Bmep is generally a measure of load, and piston speed a measure of potential wear and maintenance. Although the introduction of the turbocharged and intercooled engine has somewhat changed the consideration given these factors, it is still important to consider them in selecting engines where long life is a factor.

Maintenance of engines has been considered by some as objectionable and more costly than electric power. A recent innovation of engine manufacturers, in the form of a service contract for installations where trained personnel are not available or desirable for economic reasons, can eliminate these objections and costs. The complete maintenance of the engine is done on a fixed-fee basis for a designated period of time.

The exhaust gases of spark ignition and compression ignition (diesel) engines contain pollutants that for many engine applications are increasingly the subject of legislation restricting the quantity of pollutants the engine can emit. Examples of pollutants are carbon monoxide (CO), oxides of nitrogen (NO_x), unburned hydrocarbons (HC), and, for diesels, particulates in the form of carbon soot. Pollutants can be measured on a specific basis, such as g/bhp-hr and ppm (parts per millions by volume), or on a site basis, such as lb/hr or tons/year. Engine manufacturers are designing “clean” engines that incorporate features to minimize the formation of pollutants during combustion and may include catalytic converters and particulate filters in the exhaust system to further reduce the pollutants emitted in the exhaust gases.

The remaining conditions listed previously will be discussed in detail later.

FUEL SYSTEMS

Gasoline Gasoline is used primarily with standby pumping units. Inasmuch as the spark ignition system first introduced the internal combustion engine to power applications, gasoline was used as the primary fuel. Commercial gasoline has an average heating value of 19,000 Btu/lb (44.2 MJ/kg). It is easy to transport and handle and, unlike gaseous fuels, does not require pressure storage and regulating equipment. The starting capabilities of a gasoline engine are satisfactory, provided the engine is in good operating condition. With the high-power engine of today, refinery control can produce a fuel matched to the operating conditions.

Gasoline does have some disadvantages that are reducing its use as an engine fuel. In small-volume usage, it is safe and easily handled. In larger volumes, it becomes expensive and hazardous. Because it is not entirely stable, it will deteriorate when exposed to gums and resins in storage over a period of time. There is also the possibility of condensation of water in the fuel, which is detrimental to good operation. The danger of fire is always present because of leaks in the system. Finally, the increased production and distribution of gasoline have made it a target of increasing taxation, making it economically prohibitive in many installations.

Gas A gaseous fuel system using natural gas, LPG, or sewage gas may be a simple manually controlled system, such as a gasoline engine, or a carefully engineered automatic system. The basic gas carburetion system consists of a carburetor and pressure regulator mounted on the engine. A gas distribution system, like a water supply system, must be at some designated pressure and flow, and so a field pressure regulator is required. The characteristics of this regulator will depend upon the gas analysis, the displacement of the engine, the speed range, and local regulations. A typical schematic of a gas fuel system is shown in Figure 3. The location of the regulator is generally under the jurisdiction of the gas utility that supplies it. In most cases, a single field regulator is all that is required, but at times this can cause problems. For example, subsequent installation of gas-burning equipment used intermittently may cause gas pressure regulation not compatible with the small amount required for pilot lighting. A single regulator installed some distance from the engine could result in hard starting because the engine vacuum is not sufficient for a full gas flow. To eliminate this problem, the initial regulator is set at a higher pressure in order to give a readily available supply of fuel for all devices.

Natural gas has an average heating value of 800 to 1000 Btu/ft³ (29.8 to 37.3 MJ/m³). Commercial butane has a value of 2950 Btu/ft³ (110 MJ/m³), and propane a value of 3370 Btu/ft³ (126 MJ/m³). Commercial LPG fuel, which is a mixture of butane and propane, varies in both amount and corresponding heating value.

LPG fuel is produced by mechanical and compression processes, and the methods of distribution and handling must meet regulations. Natural gas is usually supplied under moderate pressures, seldom exceeding 50 lb/in (345 kpa), whereas LPG fuel is supplied as

FIGURE 3 Typical natural gas fuel system (Waukesha Motor)

FIGURE 4 Typical LPG fuel system (Waukesha Motor)

a liquid under pressures as high as 200 lb/in² (1380 kPa) in warm weather. As a result, natural gas will readily mix with air and burn, whereas LPG fuel must be changed from a liquid to a vapor with the addition of heat, as shown in Figure 4.

As a natural process in the modern waste-treatment plant, sewage gas may be produced in the sewage digester. This gas has the same basic qualities as natural gas and is composed of about 65 to 70% methane. It has a heating value of 550 to 700 Btu/ft³ (20.5 to 26.1 MJ/m³). The same basic carburetion system used for natural gas is used. Sewage gas contains inert substances, particularly hydrogen sulfide or free sulfur, which in the presence of free moisture or moisture resulting from combustion will form sulfurous acid, which is corrosive and thus damaging to the valves, pistons, and cylinder walls of an engine. An engine can tolerate from 10 to 30 g of sulfur per 100 ft³ (350 to 1100 g per 100 m³). Beyond this, a filtering system to remove the sulfur and moisture is advisable.

Diesel The diesel engine over the years has been used for larger power systems. The initial cost of the system is justified to an extent by lower cost of the fuel. The better fuel economy of the diesel engine and its torque characteristics also are important factors in the selection of this fuel for many applications. Diesel fuel has one distinct advantage: it does not form the dangerous fuel vapors that other fuels do. It does require, however, a good fuel-filtering system because of contaminants in the fuel that can create problems for the precision design of the fuel-injection system.

Commercial diesel fuels are the residue that remains after the more volatile fractions of crude oil have been removed. The heating value is generally about 19,000 Btu/lb (44 MJ/kg). In the diesel engine, the fuel is injected into the cylinder at the end of the compression stroke in an atomized form. The compression stroke results in a temperature sufficient to ignite the fuel without the use of any ignition device. Although fuel systems from different engine manufacturers vary, the basic components are the same.

The larger diesel engines may be designed to operate on a dual fuel system. The engine operates on five gaseous fuels with a pilot injection of diesel fuel for ignition. In case of a loss of the gaseous fuel supply, the engine will convert to 100% diesel fuel.

Relative Performance Curves Typical performance curves comparing power, torque, and part-load fuel economy are shown in Figure 5.

COOLING SYSTEMS

Cooling is essential in all internal combustion engines because only a small portion of the total heat energy of any fuel is converted to useful energy. The remainder is dissipated into

FIGURE 5A Gasoline engine performance curves: (A) maximum, (B) intermittent, (C) continuous ratings of engines with accessories (Waukesha Motor)

the coolant, exhaust, and lubricating oil and by radiation. A hypothetical heat balance is shown in Figure 6.

Specific data and recommendations on cooling requirements vary from one manufacturer to another. In general, the heat rejection to an engine cooling system will range between 30 to 60 Btu/hp · min (25 to 51 MJ/kWh) for diesel engines and up to 70 Btu/hp · min (59 MJ/kWh) for natural gas and gasoline engines. This heat must be transferred to some form of heat-exchange medium.

In designing any cooling system, certain factors must be considered:

- Additional heat from driven equipment, such as the cooling of speed-reducing or -increasing gears where the engine coolant is the medium
- Water-cooled exhaust manifolds on the engines or water-cooled exhaust turbochargers or after-coolers
- High ambient temperatures or heat from nearby equipment

FIGURE 5B Gas engine performance curves: (A) maximum, (B) intermittent, (C) continuous ratings of engines with accessories (Waukesha Motor)

- Variation in the heat-exchanger coolant temperature
- Entrapment of substantial quantities of air in the coolant water
- Inability to maintain a clean cooling system

With any cooling system, one of the most important factors of design is the temperature drop across the engine. Most engine manufacturers desire a temperature differential of no more than 10 to 12°F (5.6 to 6.7°C), and closer values are desirable. A jacket-water temperature across the engine of 170°F (77°C) is preferred, and in high-temperature or waste-heat-recovery systems, temperatures of 200°F (93°C) or more are common and not harmful.

Radiator The radiator cooling system is perhaps the most common and best understood method of cooling. It is based on a closed system of tubes through which the jacket water passes. The heat is dissipated by a fan, creating a stream of moving air passing through

FIGURE 5C Diesel engine performance curves: (A) maximum, (B) intermittent, (C) continuous ratings of engines with accessories (Waukesha Motor)

the tubes. The fan is driven either by the engine or by an auxiliary source of power (Figure 7).

An engine in a fixed outside installation can be cooled without much difficulty. Certain factors must be considered, such as ambient temperature, direction of the prevailing wind, and presence of foreign airborne materials. In high temperatures (usually above 110°F [48°C]), a larger radiator is required. If the prevailing winds are extremely high, the unit can be located to offset normal fan flow. Screening can be used to prevent the clogging of the air passes in the radiator where the atmosphere tends to contain foreign airborne material, such as dust.

Radiator cooling may be used in an inside installation, but there are certain problems which, unless properly anticipated, limit this system. The recirculation of cooling air and the radiation of exhaust heat from the engine create a problem. As was previously pointed out, every 10°F (5.6°C) rise above 60°F (15.6°C) results in a 1% loss in power. When 5 to 10% of the total heat put into an engine is radiated, some means of power ventilation must

FIGURE 6 Hypothetical heat balance (Waukesha Motor)

FIGURE 7 Radiator cooling system (Waukesha Motor)

FIGURE 8 Radiator cooling system for an inside installation (Waukesha Motor)

be provided to remove this heat through ducts, louvers, or forced ventilation with a separate fan. An installation of this type is illustrated in Figure 8.

Heat Exchanger The heat exchanger cooling system (Figure 9) is the best system for a stationary engine installation. Using a tube bundle in a closed shell, the cooling exchange medium is water (often called raw water). This water may be plant or process water; it may be recirculated or, in standby installations, allowed to pass to waste. The system has the advantage of the radiator cooling system in that it is self-contained: the quantity and quality of the water in the engine can be controlled. It has the further advantage of not being affected by the flow of heat to air movement if the heat of radiation is taken into account in the design of the system. On the other hand, the cooling medium, unless used in a plant system, is a disadvantage because it is costly. A separate pump is required to provide the necessary water for cooling unless city water or process water is under sufficient pressure.

City Water and Standpipe City water cooling is designed to take water directly from the city main or from the pump the engine is driving. It is used on some emergency or standby installation. It is simple and inexpensive, gives unlimited cooling for moderate-size engines, is easily understood, and will operate instantly in an emergency. On the negative side, the cooling water is wasted, corrosive elements may be introduced into the engine jacket water system, and it may create excessive temperature changes across the engine jacket.

Standpipe cooling (Figure 10) is basically the same as city water cooling except that a thermostatic valve is employed to admit makeup water as required. The vertical pipe is a

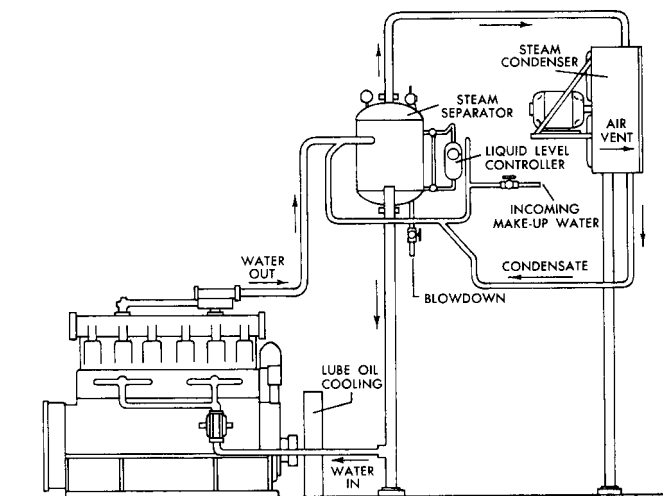

FIGURE 11 High-temperature cooling system (Waukesha Motor)

the engine at a temperature equal to or above its atmospheric boiling point and under sufficient pressure to remain liquid until discharged from the engine into a flash chamber, where a drop in pressure causes the formation of steam, which is condensed and returned to the engine at very near the discharge temperature. A schematic of this system is shown in Figure 11. This system has the advantages of a very small temperature differential across the engine, which minimizes distortion of all working parts, and a constant working temperature regardless of load. Because of the higher working temperatures, the combustion area and crankcase of the engine have fewer liquid by-products of combustion and corrosive materials. Of prime importance is the waste heat that can be recovered for plant process with a very small amount of makeup water for cooling.

Cooling Tower Cooling towers are used in some large or multiple-engine installations. Through the use of a current of air, produced either by a natural draft or by mechanical means, a tower causes a sensible heat flow from the cooling water to the air. Atmospheric, or natural, draft towers depend upon natural wind velocities and thus can vary widely. Mechanical draft towers, where the air supply can be controlled, can be put in any area, but the limit to their cooling capacity is the power required to operate them. As the water volume increases, the volume of air required and the pressure the fan has to operate against increase. A point is reached where the cost of installation and operation becomes prohibitive. A diagram of a system that combines components of the cooling systems mentioned plus the waste-heat recovery system silencer, to be mentioned later, is shown in Figure 12.

AIR-INTAKE SYSTEMS

A most important consideration in the application of an engine to any pump drive is the engine's ability to "breathe." As air is required for combustion, the design engineers of any project must take into account the necessary provisions for this air. The environment, the service, the speed range of the engine, the duty cycle, and the location from which the combustion air is to be taken are of vital importance.

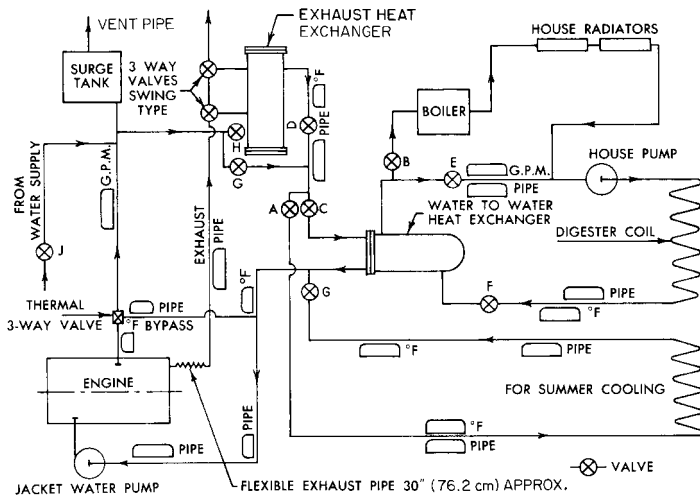

FIGURE 12 Complete cooling system, including waste-heat recovery (Waukesha Motor)

The first step in the selection of any intake system is to determine the volume of air, in cubic feet per minute (cubic meters per second) required for combustion, which may be calculated by the formula:

$$V_{\text{ideal}} = \frac{B^2 \times S \times \text{rpm} \times N}{C \times K}$$

where B = cylinder bore, in (cm)

S = piston stroke, in (cm)

rpm = engine speed, revs/minute

N = number of cylinders

$C = 2,200$ for V_{ideal} in CFM or 76.39×10^6 for V_{ideal} in m^3/s

$K = 1$ for two-stroke cycle and 2 for four-stroke cycle

Volumetric efficiency, defined as the ratio of actual air flow to ideal air flow, will vary with engine design, but an average of 80% may be used to determine the air cleaner size. Two-stroke cycle engines will require approximately 140% air flow calculated by the above equation. For supercharged and turbocharged engines, the air flow requirements should be obtained from the manufacturer.

The two basic cleaners available are wet and dry. The wet, or oil-bath, cleaner consists of either an oil wire mesh or an oil bath through which the air must pass. A dry cleaner uses a paper or cloth filter that traps dust, lint, and so on but allows the air to pass through.

The installation of a suitable air cleaner is important. In cases where adequate air can be supplied through proper ventilation of the area surrounding the engine, it is best to mount the cleaner on the engine. If it is necessary to bring air to the engine from outside the area of the building, certain design factors must be considered. The pipe connections from an outside cleaner should be tight and mechanically strong, and fabric hose should not be used unless the length is relatively short. The air to the engine should not be heated by close proximity to the engine or any other heating device because, as previously mentioned, power loss occurs with air temperatures above 60°F (15.6°C). To avoid restrictions

in the system, there should be no sharp bends in the piping. Finally, any outside air cleaner must be designed so moisture such as rain or snow cannot enter the system.

The air cleaner system on a turbocharged engine must be able to remove any impurities in the air that would be detrimental to the efficiency of the turbocharger. Because of the increased air requirements, a larger air-cleaner system must be used on such units.

EXHAUST SYSTEMS

An engine consumes a large volume of air for combustion, and that volume must be removed after combustion. It is necessary that the exhaust back pressure be kept at a minimum while this volume is being removed. The exhaust piping should be properly sized, and long sweep elbows should be employed if necessary. Unless the back pressure is kept low, the following conditions can result:

- Loss of power
- Poor fuel economy
- High combustion temperatures with increased maintenance
- High jacket water temperatures
- Crankcase sludging with resulting corrosion and bearing wear

All internal combustion engines create noise. Depending upon the location of the engine, this noise can be a problem. Normally, when measured from a distance of about 10 ft (3 m), an unmuffled engine creates a decibel noise level ranging from 100 for the small- and medium-size engine to 125 for the larger engine. Thus most engine installations incorporate some form of exhaust silencer, or muffler. Depending upon the degree of silencing, a muffler will reduce the unmuffled decibel reading by 30 to 35 dB. Various types are manufactured to meet the required conditions and are classified as follows:

- Standard or industrial
- Semiresidential (high-degree)
- Residential or hospital (supercritical)

The basic exhaust silencer is designed as either a dry type or wet type. The latter is used in installations such as sewage or water treatment plants, where the recovery of heat for plant processes is important. Basically this type may be classified as a low-pressure boiler. Water is admitted to the silencer through tubes or coils to pick up the heat from the exhaust. As shown in Figure 6, approximately 30% of the total heat input into the engine is exhausted. The wet-type silencer is designed to regain about 60 to 70% of this heat. This silencer has an advantage in its ability to operate either wet or dry. Thus when heat is not required, it may be operated dry and vice versa.

STARTING SYSTEMS

Starting methods for engines fall into two broad categories: direct and auxiliary.

Direct The direct system, used primarily with large engines, employs some means of exerting a rotating force on the crankshaft, such as the introduction of high-pressure air directly into the cylinders of the engine. A direct system on small air- or water-cooled engines using either a rope or a hand crank has to a large extent been discarded in favor of an auxiliary method.

Auxiliary The auxiliary system employs a small gear that meshes with a larger gear (ring gear) on the engine flywheel. The ratio of the number of gear teeth on the large gear

to those on the small gear is called the *cranking ratio*. Generally, the larger the ratio, the better the cranking performance. The auxiliary system uses several means to drive the small gear:

- Electric motor
- Air motor
- Hydraulic motor
- Auxiliary engine

ELECTRIC MOTOR The electric motor may be either dc or ac. The dc motor most commonly used is available in 6, 12, 24, or 32 V. The voltage size will depend upon the size of the engine, the ambient temperature, and the desired cranking speed of the engine. The dc system requires a source of outside power, usually in the form of a storage battery. To assure prompt starting, a charging system for the battery is required in the form of either a charging generator driven by the engine or an ac-powered battery trickle charger. The latter is recommended for standby installations where an engine-driven charging generator functions only when the engine is operating. During idle periods, the battery will lose its charge unless maintained by a trickle charger. In recent years, there has been a trend toward the use of an ac generator, or alternator, which has the advantages of small size, higher voltage and amperage, competitive price, and good charging ability under idle speed conditions.

Another type of electric motor is a line voltage starter available in 110, 220, or 440V ac. It has the advantages of faster and more powerful cranking, the elimination of the battery and charging system, less maintenance, and sustained cranking through unlimited available electric power. Its disadvantages are a higher initial cost, the requirement of high line voltage at the site, the danger to personnel due to the high voltage, and the requirement to conform to existing wiring and installation codes.

AIR MOTOR The air motor, which is usually of the rotary-vane type, uses high-pressure air in the range of 50 to 150 lb/in² (340 to 1030 kPa) to turn it in starting the engine. It is mounted on the engine flywheel housing to mesh with the gear on the flywheel in the same manner as the electric motor. An outside source of air from an air compressor, usually with a 250-lb/in² (1720-kPa) capacity, is required. A pressure-reducing valve is installed in the line to the engine. The high-pressure air stored in an adequate receiver is sufficient for several starting cycles. This starting system has the advantages of faster cranking, sustained cranking as long as the air supply lasts, suitability in hazardous locations where an electric system might be dangerous, and ability to operate on either compressed air or high-pressure natural gas. Its disadvantages include a higher initial cost, the requirement of an air-compressor system, and, finally, a shutdown condition if the air supply is depleted before the engine starts.

HYDRAULIC MOTOR The hydraulic motor system consists of the motor, an oil reservoir, an accumulator, and some means of charging the accumulator. The accumulator, which is a simple cylinder with a piston, is charged on one side with nitrogen gas. As the hydraulic fluid, usually oil, is pumped into the other side, the gas is compressed to a very high pressure. When released, the fluid turns the motor, which in turn rotates the engine. The system can be charged by hand, with an engine-driven pump, or with an electric motor-driven pump. Generally, an engine-driven or electric-motor-driven pump is used in conjunction with the hand pump in case of an engine or electrical failure. This system has the same basic advantages of the air motor except that there is no prolonged starting. If the engine is in good operating condition, the cranking is fast and a start is instantaneous, but, if not, it is necessary to recharge the system before another start can be made.

AUXILIARY ENGINE A small auxiliary air-cooled or water-cooled engine is sometimes employed for starting. It may be mounted on the engine in the same manner as the other systems, or a belt drive may be employed. Some form of speed reduction is required to reduce the higher speed of the auxiliary engine to that required for proper cranking. The

principal advantage of such a system is a complete independence from outside sources of power, such as batteries, air, or pumps, but this is offset by a higher initial cost and the required regular maintenance of the engine.

IGNITION SYSTEMS

The internal combustion engine requires some means of igniting the combustible charge in the cylinder at the proper time. Today's high-compression gasoline and gas engines demand a system that will produce a high-tension spark across a short gap in the combustion chamber for the ignition of the charge. It is obvious that the design of the combustion chamber must be such that this combustible mixture of fuel and air is present between the discharge gap when the spark occurs; otherwise, ignition will not take place.

Ignition systems for gasoline or gas engines are considered high or low tension. The energy system for the high-tension system is either an electric generator and battery or a magneto. The generator and battery produce a direct current at 6 to 12 V potential, and the magneto produces an alternating current with higher peak voltages. With either energy source, this system has a primary circuit for the low-voltage current and a secondary circuit for the high-voltage current.

The primary circuit consists of the battery, an ammeter, an ignition switch, a primary coil, and breaker points and a condenser in the distributor. When the ignition switch and the breaker points close, a current flows through the circuit and builds up a magnetic field in the primary coil. Opening the breaker points breaks this circuit, causing the magnetic field to start collapsing. As the field collapses, it produces a current that flows in the same direction in the primary circuit and charges the condenser plates. The condenser builds up a potential opposing flow, which discharges back through the current. This results in a sudden collapse of the remaining magnetic field and the induction of a high voltage into the secondary winding of the coil. The breaker points are opened and closed by a cam which is engine-driven, usually at half engine speed.

The secondary circuit consists of the secondary coil winding, the lead to the distributor rotor, the distributor, the spark plug leads or wires, and the spark plug. A magneto eliminates the battery, but includes in its construction the balance of both primary and secondary circuits. It may have either a rotating coil and stationary permanent magnets or a stationary coil and rotating magnets. The relative movement of the primary coil winding and the magnets induces an alternating current in the primary circuit, the breaking of which induces a high-voltage current in the secondary circuit.

The development of the modern engine has required many refinements in spark plug design, but basically a spark plug consists of two electrodes, one grounded through the shell of the plug and the other insulated with porcelain or mica. The insulated electrode is exposed to the combustion. The heat flow occurs from this electrode to the spark plug shell through the grounded electrode.

Recent developments in ignition systems have produced the low-tension and breakerless systems. The breakerless system has eliminated most of the moving parts in the distributor system. The breaker points in the distributor system are actually a switch that opens and closes the primary circuit of an ignition coil. In the breakerless system, the use of solid-state devices provides a switch with no moving parts to wear or require adjustment.

The low-tension magneto system has been developed to reduce electrical stresses in the ignition circuit. The secondary coil has been removed from the magneto proper and relocated near each spark plug. The low voltage generated by the magneto is transmitted through the wiring harness to secondary coils, which then step up to the voltage to be transmitted through short leads to the spark plug. These leads may be insulated to withstand the stresses imposed upon them. This results in a minimum of electrical stresses with a resulting longer life of all components of the system.

As was mentioned previously under fuel systems, the diesel engine used the heat of compression for ignition; thus no auxiliary systems, such as the systems mentioned above, are required. The fuel is injected into the combustion chamber under relatively high pressure through the use of a fuel pump and injection nozzle. This system may be either an

individual pump and nozzle for each cylinder, commonly called a *unit injection*, or a multicylinder pump that maintains a high pressure in a common fuel line connected to each injection nozzle. The latter is normally called the *common rail system*.

ENGINE INSTALLATIONS

Foundation The correct foundation, mounting, vibration isolation, and alignment are most important to the success of any engine installation. All stationary engines require a foundation or mounting base. There are many variations, but all basically serve to isolate the engine from the surrounding structures and absorb or inhibit vibrations. Such a base also provides a permanent and accurate surface upon which the engine and usually the pump may be mounted.

To meet these requirements, the foundation must be suitable in size and mass, rest on an adequate bearing surface, provide an accurately finished mounting surface, and be equipped with the necessary anchor bolts.

The size and mass of the foundation will depend upon the dimensions and weight of the engine and the pump (if a common base is considered). The following minimum standards should be followed:

1. Width should exceed the equipment width and length by a minimum of 1 ft (0.3 m).
2. The depth should be sufficient to provide a weight equal to 1.3 to 1.5 times the weight of the equipment. This depth may be determined by the following formula:

$$\text{In USCS units} \quad H = \frac{(1.3 - 1.5)W}{L \times B \times 135}$$

$$\text{In SI units} \quad H = \frac{(1.3 - 1.5)W}{L \times B \times 2162}$$

where H = depth of foundation, ft (m)

W = weight (mass) of equipment, lb (kg)

L = length of foundation, ft (m)

B = width of foundation, ft (m)

135 = density of concrete, lb/ft³ (2162 kg/m³)

The soil-bearing load in pounds per square foot (kilograms per square meter) should not exceed the building standard codes. It may be calculated by the formula

$$\text{Bearing load} = \frac{(2.3 - 2.5)W}{B \times L}$$

Foundation or anchor bolts used to hold the equipment in place should be of SAE grade No. 5 bolt material or equivalent. The diameter, of course, is determined by the mounting holes of the equipment. The length should be equivalent to a minimum embedded length of 30 times the diameter plus the necessary length for either a J or an L hook. An additional 5 to 6 in (13 to 15 cm) should be provided above the top surface of the foundation for grout, sole plate, chocks, shims, equipment base washers, and nuts, plus small variations in the surface level. Around the bolts, it is a good practice to place a sleeve of iron pipe or plastic tubing to allow some bending of the bolts to conform with the mounting hole locations. This sleeve should be about two-thirds the length of the bolt, with its top slightly above the top surface of the foundation to prevent concrete from spilling into the sleeve.

Sole plates running the length of the equipment are recommended for mounting directly to the foundation. Made of at least $\frac{3}{4}$ -in (19-mm) hot- or cold-rolled steel and a

width equivalent to the base-foot mounting of the equipment, they will provide a level means of mounting and will avoid variations in the level of the concrete. These plates should be drilled for the mounting holes and drilled and tapped for leveling screws, which will permit the plates to be leveled and held during the pouring of grout.

Alignment Although the alignment will vary with the type of engine and the pumping equipment, the basic objective remains the same. The driven shaft should be concentric with the driver shaft, and the centerlines of the two shafts should be parallel to each other. Rough alignment should be made through the use of chocks and shims. A dial indicator should be used to check deflection by loosening or tightening the anchor bolt nuts until there is less than a 0.005-in (0.13 mm) reading at each bolt. Shims should be added or removed to arrive at this point. A final check should be made with all the conditions "hot," as the engine and its driven equipment expand at the rate of $0.000006 \text{ in}/^{\circ}\text{F}$ ($0.27 \mu\text{m}/^{\circ}\text{C}$) above ambient hot to cold. Although the coupling, or driving member between the engine and the pump is not discussed in this section, it must be considered in the final alignment.

Vibration Isolation It is desirable to isolate the engine, and at times the pumping equipment, from the building structure because of vibrations. Cork (Figure 13) is used in the larger and heavier installations. A combination of cork and rubber pads may be used at each mounting hole on small- or medium-size installations, and spring isolators may be used on a complete installation if flexible hoses are used for fuel, water, and air connections where required. The manufacturer of the engine and the pumping equipment should be consulted in the use of any isolating material or device.

Vibrations are closely associated with the driving and driven equipment, couplings, and other connections. These linear vibrations may be caused by improper supports of the unbalanced parts, which produce a *torsional* vibration. An understanding of this vibration is important because its elimination is the responsibility of the engine and the driven-equipment manufacturer. It is complex and cannot be detected without the use of calculations and special instruments.

The basic concept involves an elastic element, such as an engine crankshaft, which tends to twist when any firing impulses are applied. When these forces are removed, the elastic body will try to return to its original position. The driven mass and the connecting elements tend to resist these external impulses. The natural elasticity of the crankshaft and its connecting system allows a small amount of torsional deflection and tends to

FIGURE 13 Engine foundation installation (Waukesha Motor)

reduce the deflection as the external impulses reduce in force. Other reciprocating forces in the engine and external forces in the driven equipment may excite vibrations in the entire system. When all these forces come into resonance with the natural frequency of the entire system, torsional vibration will occur. This vibration may or may not be serious but, being complex, cannot be solved hastily.

The engine and pump manufacturer designs and constructs the product so critical harmonic vibrations will not be present under normal speeds and loads. However, there is no way to control the combination. An analysis of the complete system should be made. This requires a study of the mass elastic system of the combination, involving the mass weight and radius of gyration of all rotating parts. This study should be made either by the engine or pump manufacturer or by a torsional-analysis specialist.

6.1.4 HYDRAULIC TURBINES

WARREN G. WHIPPEN
HOWARD A. MAYO, JR.
DONALD R. WEBB

PUMPING APPLICATIONS

In many pumping applications, the liquid remains at a high pressure after it has completed its cycle. It is often economically desirable to recover some of the energy, which will otherwise have to be dissipated when the liquid is brought back to a lower pressure. Instead of running the liquid through a pressure-reducing valve to destroy the energy, a hydraulic turbine may be installed. This turbine can therefore assist in driving the process pumps. There are many such applications in use. Among these are the use of turbine-driven pumps in gas-cleaning operations. Here the solutions from scrubber towers are passed through turbines that in turn drive pumps. Some of the solutions involved in such a process are water saturated with carbon dioxide at a temperature of 40 to 70°F (4 to 21°C) and potassium carbonate containing dissolved carbon dioxide at a specific gravity of 1.31. A liquid at the much lower specific gravity of 0.84 has been used in power-recovery turbines in a glycol-ethylene hydration process.

One of the oldest applications of turbine-driven pumps was for fire-fighting equipment in mills having a natural head of water. The large volume of low head water was routed through a hydraulic turbine that drove the pump to pressurize a sprinkler system or provide high-pressure water to the fire-hose connections. Today, hydraulic turbines are used to drive pumps that generate fire-fighting foam.

At thermal power plants, cooling water returning from the cooling towers has been used to drive a hydraulic turbine directly connected to a pump that provides part of the cooling water. Naturally, in such an application, the power from the turbine alone is not enough to maintain the pumping system. Therefore an auxiliary power source is also required.

Turbines using oil pressure have been employed at thermal power plants. Large steam turbines obtain bearing oil and control oil pressure from a main feed pump that is directly connected to the steam turbine shaft. A small amount of the oil at this high pressure is used for the relay control, with the majority of the oil going to the bearings at a lower pressure. To reduce the oil pressure from that required by the relays to that needed by the

bearings, the oil is passed through a turbine driving a booster pump that pressurizes the oil at the intake of the main pump. At locations with high flood levels, it is preferable to locate pumps and electrical equipment above flood level. Some recent steam power plant installations have used the return from the condenser to the river (normally an appreciable drop in head) to drive a hydraulic turbine, which in turn may assist in driving the condensate pumps. Also, effluent from sewage treatment plants may have a significant discharge head.

It is often economical to use a small volume of water at a high head to move a large volume of water at a low head. Of course, the reverse application can also be accomplished. The former procedure is employed at hydroelectric projects where it is necessary to operate fishways to enable migrating fish to continue traveling upstream over the dam. The large volume of water is used both to attract the fish to the fish flume and to transport the fish to the fish ladders. An example of such an installation can be seen in Figure 1.

Turbines have also been used to start large pumping units when the hydraulic conditions are suitable. The impulse turbine, which develops maximum torque at zero speed, is especially useful for this application. The power required on such a starting turbine would be less than the power required on a starting motor to do the same job. Many electric controls can be eliminated when starting with a turbine. An illustration of this application is shown in Figure 2.

Desalinization plants have been built wherein salt is removed from seawater by pumping it through a membrane at high pressure. Only pure water goes through the membrane, with most of the sea water being used to carry away the salt. This excess high-pressure sea water is then put through a power-recovery turbine that helps to drive the high-pressure pumps.

FIGURE 1 Turbine-driven fishway pumps. High head, low volume Francis-type turbine drives a low head, high-volume propeller pump at Rocky Reach, Washington.

FIGURE 2 Impulse runner used to start a large pump. Left to right: Francis turbine, generator motor, starting impulse turbine, and two-stage double-suction storage pump (Adapted from Voith Publication 1429, J. M. Voith GmbH, Heidenheim, Germany).

It is often desirable to have the turbine and pump running at different speeds, and this has been accomplished by means of a variable-speed coupling between turbine and pump. Reliable low-speed gear increasers or reducers of up to 35,000 hp (26,000 kW) are being built by many manufacturers. In applications such as starting a pump by means of a turbine, a mechanism may be needed to disengage the turbine after the pump has been started, in order to minimize windage and friction. Disengaging couplings may be hydraulic or mechanical and may be actuated when the unit is stationary or rotating, depending on the application. However, it is possible to allow the turbine to spin in air with the pump after the pump has been started. Figure 3 is an illustration of a turbine-drive pump arrangement.

TYPES OF TURBINES

Three types of turbines will be discussed: propeller (fixed and adjustable blades), Francis, and impulse. Figures 4 to 7 are illustrations of these turbine runners. Figure 8 shows a complete Francis turbine unit. The fixed- and adjustable-blade propellers and runners are essentially the same, with the exception that the adjustable is suited to a much wider range of loading conditions. This versatility is reflected in a higher manufacturing cost for the adjustable blade. The Francis runner is much like a centrifugal pump impeller running backward. The impulse runner (or Pelton wheel) is for high-head applications. The water is first channeled through a nozzle that directs a jet of water into the bowl-shaped runner buckets. This jet then discharges into the atmosphere. When a high back pressure is present in the housing, the impulse wheel cannot discharge properly. The performance drops off rapidly as the back pressure is increased. However, it is sometimes possible to admit low air pressure into the impulse runner housing to lower the level of the liquid surface to below the level of the runner. When the high turbine back pressure cannot be eliminated, a Francis turbine will perform much better than an impulse turbine. Figure 9 illustrates the relative efficiencies of the different types of runners. The fixed-blade propeller and Francis runners operate most efficiently in a range near full load, and operating time should be limited at low loads. The impulse and adjustable-blade runners, however, are designed for high efficiencies over a large load range. The adjustable-blade propeller accomplishes this by changing the angle of its blades by means of linkage in the hub of the runner. With the impulse runner, the size of the jet is controlled by the nozzle needle, which enables the runner to maintain high efficiencies at low loads.

FIGURE 4 Mixed flow propeller runner (Voith Siemens Hydro)

TURBINE ARRANGEMENTS

As is typical with pumps, hydraulic turbines are usually arranged with their power shafts either vertical or horizontal. In recent years, several low head installations have had inclined shafts to reduce excavation costs. The large (above 10,000 hp or 7,000 kW) vertical propeller turbines with concrete water passages have not been used with pumps. This is also true with very large, high head Francis turbines with steel-lined spiral shaped water passages. Mid-size and small hydraulic turbines of all three types may have vertical or horizontal shafts and usually steel water passages when used with pumps. Horizontal shaft arrangements have the advantage of better access to each piece of equipment. They usually require a greater floor area but lower power/pump house. For low heads (under 30' or 10 meters), propeller turbine installations have used inclined shafts with Bulb and Pit generator housings. TUBE turbines with a nearly straight draft tube have also been arranged with inclined shafts. For very low heads (under 15' or 5 meters), water wheels extending the width of a spillway are being considered where conventional hydraulic turbines are too costly.

Each project or site is likely to have special conditions, which will influence selection of the optimum turbine and pump arrangement.

Flow Units The size of hydraulic turbines has become so large that the earlier conventional flow quantity of cubic feet/minute (cfm) is today cubic feet/second (cfs) or cubic meters per second (cms). The following conversions are therefore useful:

FIGURE 5 Adjustable-blade propeller runner. “Kaplan” turbines have adjustable blades coordinated with adjustable wicket gates (Voith Siemens Hydro)

FIGURE 6 Francis runner has shorter buckets than a centrifugal pump impeller (Voith Siemens Hydro)

FIGURE 7 Impulse (or Pelton) runners (Voith Siemens Hydro)

1 cfs = 449 gpm or 1.077 mgd

1 cubic foot = 7.48 US gallons

British imperial gallon = 1.2009 US gallon

1 cms = 35.3 cfs

FIGURE 8 Complete standard Francis turbine unit with spiral case and elbow draft tube: 1) Shut-off valve, 2) Spiral case, 3) Stay ring, 4) Curb ring, 5) Guide vane, 6) Turbine cover, 7) Runner, 8) Draft tube elbow, 9) Draft tube, 10) Operating ring, 11) Servomotor, 12) Lever, 13) Turbine shaft, 14) Shaft seal, 15) Bearing, 16) Flexible coupling, 17) Generator (Voith Siemens Hydro)

Specific speed This is the speed at which a runner will rotate if the runner diameter is such that, under 1 ft (1 m) net head, it will develop 1 hp (1 kW):

In USCS units
$$N_s = \frac{\text{rpm} \times \text{hp}^{1/2}}{\text{ft}^{5/4}}$$

In SI units
$$N_s = \frac{\text{rpm} \times \text{kW}^{1/2}}{\text{m}^{5/4}}$$

The specific speed is an important factor governing the selection of the type of runner best suited for a given operating range. The impulse wheels have very low specific speeds

FIGURE 9 Efficiency versus load for different runner types

relative to propellers, and the specific speed of a Francis turbine lies between the impulse and propeller. Table 1 shows some statistics for existing units.*

SIZES AND RATINGS

Although power-recovery turbines are relatively small, there are much larger turbines in existence that could be used to drive pumps. Turbines of the following sizes do exist: propeller, 405.5-in (10.3-dm) diameter; Francis, 288-in (7.3-m) diameter; and impulse, 176-in (4.5-m) diameter. The extreme range of power, head, and speed is shown in Table 2.

GENERAL CHARACTERISTICS

Sigma As in pumps, the problem of cavitation also exists in turbines. Sigma is defined as follows:

$$\sigma = \frac{H_a - H_s}{H}$$

where H_a = feet (meters) of atmospheric pressure minus vapor pressure

H_s = distance in feet (meters) the centerline of the blades is above tailwater for vertical units or distance in feet (meters) the highest point of the blade is above tailwater for horizontal units

H = feet (meters) of elevation between inlet head water surface and tailwater surface elevation

Critical sigma is defined as that point at which cavitation begins to affect the performance of the turbine. Figure 10 shows the relationship between critical sigma and specific speed and also shows which type of runner is best for a given specific speed. The impulse

*Universal specific speed Ω_s (defined in Chapter 1 and Section 2.1) is found from these turbine N_s -values as follows:

$$\Omega_s = \frac{N_s(USCS)}{4.344\sqrt{\eta_t \times \text{sp. gr.}}} = \frac{N_s(SI)}{16.564\sqrt{\eta_t \times \text{sp. gr.}}}$$

where η_t is the turbine efficiency in percent.
